Smith’s Elements of Soil Mechanics

Eighth Edition

Ian Smith
Napier University, Edinburgh
Contents

Preface viii

Notation Index x

1 Classification and Identification Properties of Soil 1
   1.1 Agricultural and engineering soil 1
   1.2 Engineering definitions 2
   1.3 Clays 4
   1.4 Soil classification 6
   1.5 Common types of soil 15
   1.6 Soil classification and description 16
   1.7 Soil properties 23
   1.8 Soil physical relations 33
   Exercises 34

2 Soil Water, Permeability and Flow 37
   2.1 Subsurface water 37
   2.2 Flow of water through soils 39
   2.3 Darcy’s law of saturated flow 40
   2.4 Coefficient of permeability (k) 40
   2.5 Determination of k in the laboratory 41
   2.6 Determination of k in the field 45
   2.7 Approximation of k 48
   2.8 General differential equation of flow 48
   2.9 Potential and stream functions 50
   2.10 Flow nets 52
   2.11 Hydraulic gradient 52
   2.12 Calculation of seepage quantities from a flow net 54
   2.13 Drawing a flow net 55
   2.14 Critical hydraulic gradient, i_c 57
   2.15 Seepage forces 58
   2.16 Alleviation of piping 58
   2.17 Design of filters 59
   2.18 Total and effective stress 63
   2.19 Capillarity 64
   2.20 Earth dams 67
   2.21 The problem of stratification 73
   2.22 Calculation of seepage quantities in an anisotropic soil 75
   2.23 Permeability of sedimentary deposits 78

</table>
It took a whole quarter of a century to get there, but at last, in December 2004, the long-awaited Eurocode 7: Geotechnical design – Part 1: General rules was finally published. This European design standard is to be fully adopted by 2010 and its introduction and subsequent implementation mean a radical change to all aspects of geotechnical design across Europe. This affects practising engineers, university lecturers of geotechnical engineering and, of course, all students undertaking courses in civil engineering. The long-established, traditional approaches to geotechnical design must now be moved to one side to make way for the new limit state design approach advocated in Eurocode 7. This is a daunting thought for lecturers and students alike and so I have endeavoured to make the understanding of the new Code as simple and painless as possible by introducing it in this, the eighth edition of Elements of Soil Mechanics. Through several worked examples and clear explanatory text, the philosophy of Eurocode 7 and its design approaches are set out covering a whole range of topics including slope stability, retaining walls and shallow and deep foundations.

To help the reader follow many of the principles and worked examples in the book, I have produced a suite of spreadsheets and portable documents to accompany the book. The spreadsheets match up against many of the worked examples and these can be used by the reader to better understand the analysis being adopted in the worked example. This, I hope, will be particularly beneficial to understanding the Eurocode 7 design examples. In addition, I have produced the solutions to the exercises at the end of the chapters as a series of portable document format (pdf) files. All of these files can be freely downloaded from: http://sbe.napier.ac.uk/esm.

Whilst the introduction of Eurocode 7 has driven the bulk of the new material in this edition, I have also updated other aspects of the text throughout. This was done in recognition that some aspects of the book had become dated as a result of the introduction of new methods and standards. Furthermore, the format of the book has been improved to aid readability and thus help the reader in understanding the material. All in all, I believe I have produced a valuable and very up-to-date textbook on soil mechanics from which the learning of the subject should be made easier.

I must thank Dr Andrew Bond, Director of Geocentrix and UK delegate on the Eurocode 7 committee, for his feedback during the preparation of the material for the chapters dealing with Eurocode 7. Also, thanks must go to my colleague Dr John McDougall for his advice on the revisions I have made to the chapter on unsaturated soils.
G. N. Smith, 1927–2002

In April 2002 my father died. This edition of the book would not have been written had it not been for the popularity of the earlier editions that he wrote, and I am grateful that I had the opportunity to write this edition based on his previous accomplishment. This edition is as much his work as mine.

Ian Smith
October 2005
Notation Index

The following is a list of the more important symbols used in the text.

A  Area, pore pressure coefficient
A'  Effective foundation area
A_b  Area of base of pile
A_t  Area ratio
A_s  Area of surface of embedded length of pile shaft
B  Width, diameter, pore pressure coefficient
B'  Effective foundation width
C  Cohesive force, constant
C_c  Compression index, soil compressibility
C_t  Static cone resistance
C_v  Constant of compressibility
C_s  Uniformity coefficient
C_v  Void fluid compressibility
D  Diameter, depth factor, embedded length of pile
D_10  Effective particle size
E  Modulus of elasticity, efficiency of pile group
E_d  Eurocode 7 design value of effect of actions
E.dst;d  Eurocode 7 design value of effect of destabilising actions
E.stb;d  Eurocode 7 design value of effect of stabilising actions
F  Factor of safety
F_b  Factor of safety on pile base resistance
F_axd  Eurocode 7 design axial compression load on a pile
F_a  Eurocode 7 design value of an action
F_rep  Eurocode 7 representative value of an action
F_s  Factor of safety on pile shaft resistance
G.dst;d  Eurocode 7 design value of destabilising permanent vertical action (uplift)
G_s  Particle specific gravity
G.stb;d  Eurocode 7 design value of stabilising permanent vertical action (uplift)
G_s'  Eurocode 7 design value of stabilising permanent vertical action (heave)
GWL  Groundwater level
H  Thickness, height, horizontal load
I  Index, moment of inertia
I_L  Liquidity index
I_p  Plasticity index
I_v  Vertical stress influence factor

</tbody>
</table>
\( p_0 \)  Earth pressure at rest
\( p'_m \)  Preconsolidation pressure (isotropic)
\( p'_o \)  Effective overburden pressure
\( p_p \)  Passive earth pressure
\( q \)  Unit quantity of flow, deviator stress, uniform surcharge
\( q_s \)  Safe bearing capacity
\( q_u \)  Ultimate bearing capacity
\( q_{u,\text{net}} \)  Net ultimate bearing capacity
\( r \)  Radius, radial distance, finite difference constant
\( r_u \)  Pore pressure ratio
\( s \)  Suction value of soil, stress parameter
\( s_c, s_q, s_y \)  Shape factors
\( s_w \)  Corrected drawdown in pumping well
\( t \)  Time, stress parameter
\( u, u_w \)  Pore water pressure
\( u_a \)  Pore air pressure, pore pressure due to \( \sigma_1 \) in a saturated soil
\( u_d \)  Pore pressure due to \((\sigma_1 - \sigma_3)\) in a saturated soil
\( u_{\text{d},\text{total}} \)  Eurocode 7 design value of destabilising total pore water pressure
\( u_i \)  Initial pore water pressure
\( v \)  Velocity, specific volume
\( w \)  Water, or moisture, content
\( w_L \)  Liquid limit
\( w_p \)  Plastic limit
\( w_s \)  Shrinkage limit
\( x \)  Horizontal distance
\( y \)  Vertical, or horizontal, distance
\( z \)  Vertical distance, depth
\( z_o \)  Depth of tension crack

\( \alpha \)  Angle, pile adhesion factor
\( \beta \)  Slope angle
\( \Gamma \)  Eurocode 7 over-design factor, specific volume at \( \ln P' = 0 \)
\( \gamma \)  Unit weight (weight density)
\( \gamma' \)  Submerged, buoyant or effective unit weight (effective weight density)
\( \gamma_{\text{a},\text{total}} \)  Eurocode 7 partial factor: accidental action – unfavourable
\( \gamma_b \)  Bulk unit weight (bulk weight density), Eurocode 7 partial factor: pile base resistance
\( \gamma'_c \)  Eurocode 7 partial factor: effective cohesion
\( \gamma_{cu} \)  Eurocode 7 partial factor: undrained shear strength
\( \gamma_d \)  Dry unit weight (dry weight density)
\( \gamma_f \)  Eurocode 7 partial factor for an action
\( \gamma_{f},\text{total} \)  Eurocode 7 partial factor: permanent action – unfavourable
\( \gamma_{f},\text{total} \)  Eurocode 7 partial factor: permanent action – favourable
\( \gamma_M \)  Eurocode 7 partial factor for a soil parameter
\( \gamma_{q,\text{total}} \)  Eurocode 7 partial factor: variable action – unfavourable
\( \gamma_{qa} \)  Eurocode 7 partial factor: unconfined compressive strength
Notation Index

\( \gamma_R \)  Eurocode 7 partial factor for a resistance
\( \gamma_{Re} \)  Eurocode 7 partial factor: earth resistance
\( \gamma_{Rh} \)  Eurocode 7 partial factor: sliding resistance
\( \gamma_{Re} \)  Eurocode 7 partial factor: bearing resistance
\( \gamma_s \)  Eurocode 7 partial factor: pile shaft resistance
\( \gamma_{sat} \)  Saturated unit weight (saturated weight density)
\( \gamma_t \)  Eurocode 7 partial factor: pile total resistance
\( \gamma_w \)  Unit weight of water (weight density of water)
\( \gamma' \)  Eurocode 7 partial factor: weight density
\( \gamma'_{d} \)  Eurocode 7 partial factor: angle of shearing resistance
\( \delta \)  Ground–structure interface friction angle
\( \varepsilon \)  Strain
\( \theta \)  Angle subtended at centre of slip circle
\( \kappa \)  Slope of swelling line
\( \lambda \)  Slope of normal consolidation line
\( \mu \)  Settlement coefficient, one micron, Poisson’s ratio
\( \xi_1, \xi_2 \)  Eurocode 7 correlation factors to evaluate results of static pile load tests
\( \xi_3, \xi_4 \)  Eurocode 7 correlation factors to derive pile resistance from ground investigation results
\( \rho \)  Density, settlement
\( \rho' \)  Submerged, buoyant or effective density
\( \rho_b \)  Bulk density
\( \rho_c \)  Consolidation settlement
\( \rho_d \)  Dry density
\( \rho_i \)  Immediate settlement
\( \rho_{sat} \)  Saturated density
\( \rho_w \)  Density of water
\( \sigma \)  Total normal stress
\( \sigma' \)  Effective normal stress
\( \sigma'_v, \sigma'_a \)  Total, effective axial stress
\( \sigma'_e \)  Equivalent consolidation pressure (one-dimensional)
\( \sigma_{oct} \)  Octahedral normal stress
\( \sigma_1, \sigma'_1 \)  Total, effective radial stress
\( \sigma_{shv} \)  Eurocode 7 design value of stabilising total vertical stress
\( \sigma'_y \)  Effective overburden pressure
\( \sigma'_y \)  Average effective overburden pressure
\( \sigma_1, \sigma_2, \sigma_3 \)  Total major, intermediate and minor stress
\( \sigma'_1, \sigma'_2, \sigma'_3 \)  Effective major, intermediate and minor stress
\( \tau \)  Shear stress
\( \tau_{oct} \)  Octahedral shear stress
\( \phi \)  Angle of shearing resistance with respect to total stresses
\( \phi' \)  Angle of shearing resistance with respect to effective stresses
\( \phi'_{cd} \)  Design value of critical state angle of shearing resistance
\( \phi'_{d} \)  Design value of \( \phi' \)
\( \chi \)  Saturation parameter
\( \psi \)  Angle of back of wall to horizontal
Chapter 8

Bearing Capacity of Soils

8.1 Bearing capacity terms

The following terms are used in bearing capacity problems.

*Ultimate bearing capacity*

The value of the average contact pressure between the foundation and the soil which will produce shear failure in the soil.

*Safe bearing capacity*

The maximum value of contact pressure to which the soil can be subjected without risk of shear failure. This is based solely on the strength of the soil and is simply the ultimate bearing capacity divided by a suitable factor of safety.

*Allowable bearing pressure*

The maximum allowable net loading intensity on the soil allowing for both shear and settlement effects.

8.2 Types of foundation

*Strip foundation*

Often termed a *continuous footing* this foundation has a length significantly greater than its width. It is generally used to support a series of columns or a wall.

*Pad footing*

Generally an individual foundation designed to carry a single column load although there are occasions when a pad foundation supports two or more columns.

*Raft foundation*

This is a generic term for all types of foundations that cover large areas. A raft foundation is also called a *mat foundation* and can vary from a fascine mattress supporting a farm road to a large reinforced concrete basement supporting a high rise block.
Pile foundation

Piles are used to transfer structural loads to either the foundation soil or the bedrock underlying the site. They are usually designed to work in groups, with the column loads they support transferred into them via a capping slab.

Pier foundation

This is a large column built up either from the bedrock or from a slab supported by piles. Its purpose is to support a large load, such as that from a bridge. A pier operates in the same manner as a pile but it is essentially a short squat column whereas a pile is relatively longer and more slender.

Shallow foundation

A foundation whose depth below the surface, $z$, is equal to or less than its least dimension, $B$. Most strip and pad footings fall into this category.

Deep foundation

A foundation whose depth below the surface is greater than its least dimension. Piles and piers fall into this category.

8.3 Analytical methods for the determination of the ultimate bearing capacity of a foundation

The ultimate bearing capacity of a foundation is given the symbol $q_u$, and there are various analytical methods by which it can be evaluated. As will be seen, some of these approaches are not all that suitable but they still form a very useful introduction to the study of the bearing capacity of a foundation.

8.3.1 Earth pressure theory

Consider an element of soil under a foundation (Fig. 8.1). The vertical downward pressure of the footing, $q_u$, is a major principal stress causing a corresponding Rankine
active pressure, p. For particles beyond the edge of the foundation this lateral stress can be considered as a major principal stress (i.e. passive resistance) with its corresponding vertical minor principal stress $\gamma z$ (the weight of the soil).

Now

$$p = qu \frac{1 - \sin \phi}{1 + \sin \phi}$$

also

$$p = \gamma z \frac{1 + \sin \phi}{1 - \sin \phi}$$

$$\Rightarrow qu = \gamma z \left( \frac{1 + \sin \phi}{1 - \sin \phi} \right)^2$$

This is the formula for the ultimate bearing capacity, $qu$. It will be seen that it is not satisfactory for shallow footings because when $z = 0$ then, according to the formula, $qu$ also $= 0$.

Bell’s development of the Rankine solution for c–$\phi$ soils gives the following equation:

$$qu = \gamma z \left( \frac{1 + \sin \phi}{1 - \sin \phi} \right)^2 + 2c \frac{1 + \sin \phi}{1 - \sin \phi} + 2c \frac{1 + \sin \phi}{1 - \sin \phi}$$

For $\phi = 0^\circ$,

$$qu = \gamma z + 4c$$

or $qu = 4c$ for a surface footing.

8.3.2 **Slip circle methods**

With slip circle methods the foundation is assumed to fail by rotation about some slip surface, usually taken as the arc of a circle. Almost all foundation failures exhibit rotational effects, and Fellenius (1927) showed that the centre of rotation is slightly above the base of the foundation and to one side of it. He found that in a saturated cohesive soil the ultimate bearing capacity for a surface footing is

$$qu = 5.52c_u$$

To illustrate the method we will consider a foundation failing by rotation about one edge and founded at a depth $z$ below the surface of a saturated clay of unit weight $\gamma$ and undrained strength $c_u$ (Fig. 8.2).
Disturbing moment about O:

\[ q_u \times LB \times \frac{B}{2} = \frac{q_u LB^2}{2} \]  

(1)

Resisting moments about O

- Cohesion along cylindrical sliding surface = \( c_u \pi LB \)
  \[ \Rightarrow \text{Moment} = \pi c_u LB^2 \]  
  (2)

- Cohesion along CD = \( c_u zL \)
  \[ \Rightarrow \text{Moment} = c_u zLB \]  
  (3)

Weight of soil above foundation level = \( \gamma zLB \)

\[ \Rightarrow \text{Moment} = \frac{\gamma zLB^2}{2} \]  

(4)

For limit equilibrium \((1) = (2) + (3) + (4)\)

i.e.

\[ \frac{q_u LB^2}{2} = \pi c_u LB^2 + c_u zLB + \frac{\gamma zLB^2}{2} \]

\[ \Rightarrow q_u = 2\pi c_u + \frac{2c_u z}{B} + \gamma z \]

\[ = 2\pi c_u \left( 1 + \frac{1}{\pi} \frac{z}{B} + \frac{1}{2\pi} \frac{\gamma z}{c_u} \right) \]

\[ = 6.28c_u \left( 1 + 0.32 \frac{z}{B} + 0.16 \frac{\gamma z}{c_u} \right) \]
Cohesion of end sectors

The above formula only applies to a strip footing, and if the foundation is of finite dimensions then the effect of the ends must be included.

To obtain this it is assumed that when the cohesion along the perimeter of the sector has reached its maximum value, \( c_u \), the value of cohesion at some point on the sector at distance \( r \) from \( O \) is \( c_r = c_u \frac{r}{B} \), as shown in Fig. 8.3.

Rotational resistance of an elemental ring, \( dr \) thick

\[
= \frac{c_u r}{B} \times \pi r \ dr
\]

Moment about \( O \) = \[
\frac{c_u r}{B} \times \pi r \ dr \times r = \pi \frac{c_u}{B} r^3 \ dr
\]

Total moment of both ends = \[
2 \int_{0}^{B} \frac{c_u}{B} r^3 \ dr
\]

\[
= 2\pi \left( \frac{c_u}{B} \right) \left( \frac{B^4}{4} \right) = \frac{\pi c_u B^3}{2}
\]

This analysis ignores the cohesion of the soil above the base of the foundation at the two ends, but unless the foundation is very deep this will have little effect on the value of \( q_u \). The term (5) should be added into the original equation.

For a surface footing the formula for \( q_u \) is:

\[
q_u = 6.28c_u
\]

This value is high because the centre of rotation is actually above the base, but in practice a series of rotational centres are chosen and each circle is analysed (as for a slope stability problem) until the lowest \( q_u \) value has been obtained. The method can be extended to allow for frictional effects but is considered most satisfactory when used for cohesive soils; it was extended by Wilson (1941), who prepared a chart (Fig. 8.4) which gives the centre of the most critical circle for cohesive soils (his technique is not applicable to other categories of soil or to surface footings).

The slip circle method is useful when the soil properties beneath the foundation vary, since an approximate position of the critical circle can be obtained from
8.3.3 Plastic failure theory

Forms of bearing capacity failure

Terzaghi (1943) stated that the bearing capacity failure of a foundation is caused by either a general soil shear failure or a local soil shear failure. Vesic (1963) listed punching shear failure as a further form of bearing capacity failure.

(1) General shear failure
The form of this failure is illustrated in Fig. 8.5, which shows a strip footing. The failure pattern is clearly defined and it can be seen that definite failure surfaces develop within the soil. A wedge of compressed soil (I) goes down with the footing, creating slip surfaces and areas of plastic flow (II). These areas are initially prevented from moving outwards by the passive resistance of the soil wedges (III). Once this passive resistance is overcome, movement takes place and bulging of the soil surface around the foundation occurs. With general shear failure collapse is sudden and is accompanied by a tilting of the foundation.

(2) Local shear failure
The failure pattern developed is of the same form as for general shear failure but only the slip surfaces immediately below the foundation are well defined. Shear failure is local and does not create the large zones of plastic failure which develop with
general shear failure. Some heaving of the soil around the foundation may occur but
the actual slip surfaces do not penetrate the surface of the soil and there is no tilting
of the foundation.

(3) Punching shear failure
This is a downward movement of the foundation caused by soil shear failure only
occurring along the boundaries of the wedge of soil immediately below the founda-
tion. There is little bulging of the surface of the soil and no slip surfaces can be
seen.

For both punching and local shear failure, settlement considerations are invariably
more critical than those of bearing capacity so that the evaluation of the ultimate
bearing capacity of a foundation is usually obtained from an analysis of general
shear failure.

Prandtl’s analysis
Prandtl (1921) was interested in the plastic failure of metals and one of his solutions
(for the penetration of a punch into metal) can be applied to the case of a foundation
penetrating downwards into a soil with no attendant rotation.

The analysis gives solutions for various values of $\phi$, and for a surface footing with
$\phi = 0$, Prandtl obtained:

$$q_u = 5.14c$$

Terzaghi’s analysis
Working on similar lines to Prandtl’s analysis, Terzaghi (1943) produced a formula
for $q_u$ which allows for the effects of cohesion and friction between the base of the
footing and the soil and is also applicable to shallow ($z/B \leq 1$) and surface founda-
tions. His solution for a strip footing is:

$$q_u = cN_c + \gamma z N_q + 0.5 \gamma B N_f$$

(6)
The coefficients \( N_c, N_q \) and \( N_\gamma \) depend upon the soil’s angle of shearing resistance and can be obtained from Fig. 8.6. When \( \phi = 0^\circ \), \( N_c = 5.7; N_q = 1.0; N_\gamma = 0 \).

\[ q_u = 5.7c + \gamma z \]

or \( q_u = 5.7c \) for a surface footing.

The increase in the value of \( N_c \) from 5.14 to 5.7 is due to the fact that Terzaghi allowed for frictional effects between the foundation and its supporting soil.

The coefficient \( N_q \) allows for the surcharge effects due to the soil above the foundation level, and \( N_\gamma \) allows for the size of the footing, \( B \). The effect of \( N_\gamma \) is of little consequence with clays, where the angle of shearing resistance is usually assumed to be the undrained value, \( \phi_u \), and assumed equal to \( 0^\circ \), but it can become significant with wide foundations supported on cohesionless soil.

Terzaghi’s solution for a circular footing is:

\[ q_u = 1.3cN_c + \gamma z N_q + 0.3\gamma BN_\gamma \quad (\text{where } B = \text{diameter}) \]
For a square footing:

\[ q_u = 1.3cN_c + \gamma zN_q + 0.4\gamma BN_c \]  

and for a rectangular footing:

\[ q_u = cN_c \left( 1 + 0.3 \frac{B}{L} \right) + \gamma zN_q + 0.5\gamma BN_c \left( 1 - 0.2 \frac{B}{L} \right) \]

Skempton (1951) showed that for a cohesive soil (\( \phi = 0^\circ \)) the value of the coefficient \( N_c \) increases with the value of the foundation depth, \( z \). His suggested values for \( N_c \), applicable to circular, square and strip footings, are given in Fig. 8.7. In the case of a rectangular footing on a cohesive soil a value for \( N_c \) can either be estimated from Fig. 8.7 or obtained from the formula:

\[ N_c = 5 \left( 1 + 0.2 \frac{B}{L} \right) \left( 1 + 0.2 \frac{z}{B} \right) \]

with a limiting value for \( N_c \) of \( N_c = 7.5(1 + 0.2B/L) \), which corresponds to a \( z/B \) ratio greater than 2.5 (Skempton, 1951).

### 8.3.4 Summary of bearing capacity formula

It can be seen that Rankine’s theory does not give satisfactory results and that, for variable subsoil conditions, the slip surface analysis of Fellenius provides the best solution. For normal soil conditions, Equations (6)–(9) can generally be used and may be applied to foundations at any depth in \( c-\phi \) soils and to shallow foundations in cohesive soils. For deep footings in cohesive soil the values of \( N_c \) suggested by Skempton may be used in place of the Terzaghi values.
8.3.5 Choice of soil parameters

As with earth pressure equations, bearing capacity equations can be used with either the undrained or the drained soil parameters. As granular soils operate in the drained state at all stages during and after construction, the relevant soil strength parameter is $\phi'$. Saturated cohesive soils operate in the undrained state during and immediately after construction and the relevant parameters are $c_u$ and $\phi_u$ (with $\phi_u$ generally assumed equal to zero). If required, the long-term stability can be checked with the assumption that the soil will be drained and the relevant parameters are $c'$ and $\phi'$ (with $c'$ generally taken as equal to zero) but this procedure is not often carried out.

Example 8.1

A rectangular foundation, 2 m x 4 m, is to be founded at a depth of 1 m below the surface of a deep stratum of soft saturated clay (unit weight = 20 kN/m$^3$).

Undrained and consolidated undrained triaxial tests established the following soil parameters: $\phi_u = 0^\circ$, $c_u = 24$ kPa; $\phi' = 25^\circ$, $c' = 0$.

Determine the ultimate bearing capacity of the foundation, (i) immediately after construction and, (ii) some years after construction.

Solution

(i) It may be assumed that immediately after construction the clay will be in an undrained state. The relevant soil parameters are therefore $\phi_u = 0^\circ$ and $c_u = 24$ kPa.

From Fig. 8.6: $N_c = 5.7$, $N_q = 1.0$, $N_\gamma = 0.0$.

$$q_u = cN_c(1 + 0.3B/L) + \gamma zN_q$$
$$= 24 \times 5.7(1 + 0.3 \times 2/4) + 20 \times 1 \times 1$$
$$= 177.3 \text{ kPa}$$

(ii) It can be assumed that, after some years, the clay will be fully drained so that the relevant soil parameters are $\phi' = 25^\circ$ and $c' = 0$.

From Fig. 8.6: $N_c = 25.1$, $N_q = 12.7$. $N_\gamma = 9.7$.

$$q_u = \gamma zN_q + 0.5\gamma B N_\gamma(1 - 0.2B/L)$$
$$= 20 \times 1 \times 12.7 + 0.5 \times 20 \times 2 \times 9.7(1 - 0.2 \times 2/4)$$
$$= 428.6 \text{ kPa}$$

Example 8.2

A continuous foundation is 1.5 m wide and is founded at a depth of 1.5 m in a deep layer of sand of unit weight 18.5 kN/m$^3$.

Determine the ultimate bearing capacity of the foundation if the soil strength parameters are $c' = 0$ and $\phi' = (i) \ 35^\circ$, (ii) $30^\circ$. 
**Solution**

(i) From Fig. 8.6: for $\phi' = 35^\circ$, $N_c = 57.8$, $N_q = 41.4$, $N_\gamma = 42.4$. For a continuous footing:

$$q_u = c'N_c + \gamma z N_q + 0.5\gamma B N_\gamma$$

$$= 18.5 \times 1.5 \times 41.4 + 0.5 \times 18.5 \times 1.5 \times 42.4$$

$$= 1737 \text{ kPa}$$

(ii) From Fig. 8.6: for $\phi' = 30^\circ$, $N_c = 37.2$, $N_q = 22.5$, $N_\gamma = 19.7$.

$$q_u = 18.5 \times 1.5 \times 22.5 + 0.5 \times 18.5 \times 1.5 \times 19.7$$

$$= 898 \text{ kPa}$$

The ultimate bearing capacity is reduced by some 48 per cent when the value of $\phi'$ is reduced by some 15 per cent.

---

**8.4 Determination of the safe bearing capacity**

**Lumped factor of safety approach**

The value of the safe bearing capacity is simply the value of the net ultimate bearing capacity divided by a suitable factor of safety, $F$. The value of $F$ is usually not less than 3.0, except for a relatively unimportant structure, and sometimes can be as much as 5.0. At first glance these values for $F$ appear high but the necessity for them is illustrated in Example 8.2, which demonstrates the effect on $q_u$ of a small variation in the value of $\phi$.

The net ultimate bearing capacity is the increase in vertical pressure, above that of the original overburden pressure, that the soil can just carry before shear failure occurs.

The original overburden pressure is $\gamma z$ and this term should be subtracted from the bearing capacity equations, i.e. for a strip footing:

$$q_{u,\text{net}} = cN_c + \gamma z (N_q - 1) + 0.5\gamma B N_\gamma$$

The safe bearing capacity is therefore the above expression divided by $F$ plus the term $\gamma z$:

$$\text{Safe bearing capacity} = \frac{cN_c + \gamma z (N_q - 1) + 0.5\gamma B N_\gamma}{F} + \gamma z$$

In the case of a footing founded in undrained clay, where $\phi_u = 0^\circ$, the net ultimate bearing capacity is, of course, $c_u N_c$. 

---
The safe bearing capacity notion is not used during design to Eurocode 7 where, as will be demonstrated in Section 8.7, conformity of the bearing resistance limit state is achieved by ensuring that the design effect of the actions does not exceed the design bearing resistance.

8.5 The effect of groundwater on bearing capacity

Water table below the foundation level

If the water table is at a depth of not less than B below the foundation, the expression for net ultimate bearing capacity is the one given above, but when the water table rises to a depth of less than B below the foundation the expression becomes:

\[ q_{u_{\text{net}}} = cN_c + \gamma z(N_q - 1) + 0.5\gamma'B_N \gamma' \]

where

\( \gamma = \) unit weight of soil above groundwater level
\( \gamma' = \) effective unit weight.

For cohesive soils, \( \phi_u \) is small and the term \( 0.5\gamma'B_N \gamma' \) is of little account, the value of the bearing capacity being virtually unaffected by groundwater. With sands, however, the term \( cN_c \) is zero and the term \( 0.5\gamma'B_N \gamma' \) is about one half of \( 0.5\gamma'B_N \gamma' \), so that groundwater has a significant effect.

Water table above the foundation level

For this case Terzaghi’s expressions are best written in the form:

\[ q_{u_{\text{net}}} = cN_c + \sigma'_v(N_q - 1) + 0.5\gamma'B_N \gamma' \]

where \( \sigma'_v = \) effective overburden pressure removed.

From the expression it will be seen that, in these circumstances, the bearing capacity of a cohesive soil can be affected by groundwater.

8.6 Developments in bearing capacity equations

Terzaghi’s bearing capacity equations have been successfully used in the design of numerous shallow foundations throughout the world and are still in use. However, they are viewed by many to be conservative as they do not consider factors that affect bearing capacity such as inclined loading, foundation depth and the shear resistance of the soil above the foundation. This section describes developments that have been made to the original equations.
8.6.1 General form of the bearing capacity equation

Meyerhof (1963) proposed the following general equation for $q_u$:

$$q_u = c N_c s_c i_c d_c + y z N_q s_q i_q d_q + 0.5 \gamma B N_s i_s d_s$$  \hspace{1cm} (10)

where

- $s_c, s_q$ and $s_r$ are shape factors
- $i_c, i_q$ and $i_r$ are inclination factors
- $d_c, d_q$ and $d_r$ are depth factors.

Other factors, $G_c, G_q$ and $G_r$ to allow for a sloping ground surface, and $B_c, B_q$ and $B_r$ to allow for any inclination of the base, can also be included when required.

It must be noted that the values of $N_c, N_q$ and $N_r$ used in the general bearing capacity equation are not the Terzaghi values. The values of $N_c$ and $N_q$ are now obtained from Meyerhof’s equations (1963), as they are recognised as probably being the most satisfactory.

$$N_c = (N_q - 1) \cot \phi, \quad N_q = \tan^2 \left( 45^\circ + \frac{\phi}{2} \right) e^{\pi \tan \phi}$$

Unfortunately there is not the same agreement about the remaining factor $N_r$ and the following expressions all have their supporters:

$$N_r = (N_q - 1) \tan 1.4 \phi \quad \text{Meyerhof (1963)}$$
$$N_r = 1.5(N_q - 1) \tan \phi \quad \text{Hansen (1970)}$$
$$N_r = 2(N_q + 1) \tan \phi \quad \text{Vesic (1973)}$$

It should be noted that Hansen suggested that the operating value of $\phi$ should be that corresponding to plane strain, which is some 10 per cent greater than the value of $\phi$ obtained from the triaxial test and normally used. With this approach Hansen’s expression for $N_r = 1.5(N_q - 1) \tan 1.1 \phi$, which applies to a continuous footing but is probably not so relevant to other shapes of footings.

In order to give the reader some guidance it can be said that the expression suggested by Vesic is being increasingly used. Further examples in this chapter will therefore use the following expressions for the bearing capacity coefficients:

$$N_c = (N_q - 1) \cot \phi$$
$$N_q = \tan^2 \left( 45^\circ + \frac{\phi}{2} \right) e^{\pi \tan \phi}$$
$$N_r = 2(N_q + 1) \tan \phi$$

Typical values are shown in Table 8.1.
8.6.2 Shape factors

These factors are intended to allow for the effect of the shape of the foundation on its bearing capacity. The factors have largely been evaluated from laboratory tests and the values in present use are those proposed by De Beer (1970):

\[ s_c = 1 + \frac{B}{L} \cdot \frac{N_q}{N_c} \]
\[ s_q = 1 + \frac{B}{L} \tan \phi \]
\[ s_f = 1 - 0.4 \frac{B}{L} \]

8.6.3 Depth factors

These factors are intended to allow for the shear strength of the soil above the foundation. Hansen (1970) proposed the following values:

<table>
<thead>
<tr>
<th>\frac{z}{B} \leq 1.0</th>
<th>\frac{z}{B} &gt; 1.0</th>
</tr>
</thead>
<tbody>
<tr>
<td>\gamma_{d_1}</td>
<td>1 + 0.4(z/B)</td>
</tr>
<tr>
<td>\gamma_{d_q}</td>
<td>1 + 2 \tan \phi (1 - \sin \phi)^2(z/B)</td>
</tr>
<tr>
<td>\gamma_{d_f}</td>
<td>1.0</td>
</tr>
</tbody>
</table>

Note: The arctan values must be expressed in radians, e.g. if \( z = 1.5 \) and \( B = 1.0 \) m then \( \arctan(\frac{z}{B}) = \arctan(1.5) = 56.3^\circ = 0.983 \) radians.

### Table 8.1 Bearing capacity factors in common use.

Example 8.3
Recalculate Example 8.1 using Meyerhof’s general bearing capacity formula.

Solution
(i) From Table 8.1, for $\phi_u = 0^\circ$, $N_c = 5.14$, $N_q = 1.0$ and $N_\gamma = 0.0$.

Shape factors:
- $s_c = 1 + (2/4)(1.0/5.14) = 1.1$
- $s_q = 1 + (2/4)\tan 0^\circ = 1.0$
- $s_\gamma = 1 - 0.4(2/4) = 0.8$

Depth factors:
- $z/B = 1/2 = 0.5$. Using Hansen’s values for $z/B \leq 1.0$:
  - $d_c = 1 + 0.4(1/2) = 1.2$
  - $d_q = 1.0$ (as $\phi_u = 0^\circ$)
  - $d_\gamma = 1.0$
  
  - $q_u = cN_c s_c d_c + \gamma z N_q s_q d_q$
  = $24 \times 5.14 \times 1.1 \times 1.2 + 20 \times 1.0 \times 1.0 \times 1.0$
  = $182.8$ kPa

(ii) From Table 8.1, for $\phi' = 25^\circ$, $N_q = 10.66$ and $N_\gamma = 10.88$.

The expressions for $s_q$ and $d_q$ involve $\phi$. These two factors will therefore have different values from those in case (i):

- $s_q = 1 + (2/4)\tan 25^\circ = 1.23$
- $d_q = 1 + 2\tan 25^\circ(1 - \sin 25^\circ)^2(1/2) = 1.16$

  - $q_u = \gamma z N_q s_q d_q + 0.5\gamma B N_\gamma s_\gamma d_\gamma$
  = $20 \times 1 \times 10.66 \times 1.23 \times 1.16 + 0.5 \times 20 \times 2 \times 10.88 \times 0.8 \times 1.0$
  = $478.3$ kPa

Example 8.4
Using a factor of safety $= 3.0$ determine the values of safe bearing capacity for cases (i) and (ii) in Example 8.3.

Solution
Case (i):

- $q_{u,net} = q_u - \gamma z = 162.8$ kPa

Safe bearing capacity = $\frac{162.8}{3} + 20 \times 1$

= $74.3$ kPa
For case (ii):

\[ q_{\text{net}} = \gamma z(N_q s_q d_q - 1) + 0.5 \gamma B N_r s_r d_r \]
\[ = 458.3 \text{ kPa} \]

Safe bearing capacity = \( \frac{458.3}{3} + 20 \times 1 \)
\[ = 172.8 \text{ kPa} \]

### 8.6.4 Effect of eccentric and inclined loading on foundations

A foundation can be subjected to eccentric loads and/or to inclined loads, eccentric or concentric.

**Eccentric loads**

Let us consider first the relatively simple case of a vertical load acting on a rectangular foundation of width \( B \) and length \( L \) such that the load has eccentricities \( e_B \) and \( e_L \) (Fig. 8.8). To solve the problem we must think in terms of the rather artificial concept of effective foundation width and length. That part of the foundation that is symmetrical about the point of application of the load is considered to be useful, or effective, and is the area of the rectangle of effective length \( L' = L - 2e_L \) and of effective width \( B' = B - 2e_B \).

In the case of a strip footing of width \( B \), subjected to a line load with an eccentricity \( e \), then \( B' = B - 2e \) and the ultimate bearing capacity of the foundation is found from either equation (6) or the general equation (10) with the term \( B \) replaced by \( B' \).

---

**Fig. 8.8**  Effective widths and area.
The overall eccentricity of the bearing pressure, e, must consider the self-weight of the foundation and is equal to:

\[ e = \frac{P \times e_p}{P + W} \]

where

- \( P \) = magnitude of the eccentric load
- \( W \) = self-weight of the foundation
- \( e_p \) = eccentricity of \( P \).

**Inclined loads**

The usual method of dealing with an inclined line load, such as \( P \) in Fig. 8.9, is to first determine its horizontal and vertical components \( P_h \) and \( P_v \) and then, by taking moments, determine its eccentricity, \( e \), in order that the effective width of the foundation \( B' \) can be determined from the formula \( B' = B - 2e \).

The ultimate bearing capacity of the strip foundation (of width \( B \)) is then taken to be equal to that of a strip foundation of width \( B' \) subjected to a concentric load, \( P \), inclined at \( \alpha \) to the vertical.

Various methods of solution have been proposed for this problem, e.g. Janbu (1957), Hansen (1957), but possibly the simplest approach is that proposed by Meyerhof (1953) in which the bearing capacity coefficients \( N_c, N_q \) and \( N_y \) are reduced by multiplying them by the factors \( i_c, i_q \) and \( i_y \) in his general equation (10).

Meyerhof’s expressions for these factors are:

\[ i_c = i_q = (1 - \alpha/90°)^2 \]
\[ i_y = (1 - \alpha/\phi)^2 \]

**Fig. 8.9** Strip foundation with inclined load.
8.7 Designing spread foundations to Eurocode 7

The design of spread foundations is covered in Section 6 of Eurocode 7. The limit states to be checked and the partial factors to be used in the design are the same as we saw when we looked at the design of retaining walls in Section 7.4.2.

In terms of establishing the bearing resistance, the code states that a commonly recognised method should be used, and Annex D of the Standard gives a sample calculation. Interestingly the depth factors are excluded in Eurocode 7 (without explanation) and for this reason they are excluded too from the solutions to Examples 8.5 and 8.6 in this chapter. Spreadsheets Example 8.5.xls and Example 8.6.xls, however, offer the choice whether to include the depth factors or not.

While the design procedure required to satisfy the conditions of Eurocode 7 involves essentially the same methods as we have seen so far in this chapter, there are a few differences listed in Annex D which can be considered for drained conditions. These concern the shape and inclination factors as well as the bearing resistance factor, \( N_q \), and are listed below:

\[
N_q = 2 (N_c - 1) \tan \phi' \quad \text{(for a rough base, such as a typical foundation)}
\]
\[
s_q = 1 + \left( \frac{B'}{L'} \right) \sin \phi' \quad \text{(for a rectangular foundation)}
\]
\[
s_q = 1 + \sin \phi' \quad \text{(for a square or circular foundation)}
\]
\[
s_q = 1 - 0.3 \left( \frac{B'}{L'} \right) \quad \text{(for a rectangular foundation)}
\]
\[
s_q = 0.7 \quad \text{(for a square or circular foundation)}
\]
\[
s_c = \frac{s_q N_q - 1}{N_q - 1} \quad \text{(rectangular, square and circle foundation)}
\]
\[
i_q = \frac{1 - i_q}{N_q \tan \phi'} \quad \text{where} \quad i_q = \left[ 1 - \frac{H}{V + A' c' \cot \phi'} \right]^m \quad \text{and} \quad i_c = i_q \left( \frac{m_i}{m} \right)
\]

where

- \( V \) = vertical load acting on foundation
- \( H \) = horizontal load (or component of inclined load) acting on foundation
- \( A' \) = design effective area of foundation

\[
m = m_B = \frac{2 + \frac{B'}{L'}}{1 + \frac{B'}{L'}} \quad \text{when } H \text{ acts in the direction of } B';
\]
\[
m = m_L = \frac{2 + \frac{L'}{B'}}{1 + \frac{L'}{B'}} \quad \text{when } H \text{ acts in the direction of } L'.
\]

Eurocode 7 also states that the vertical total action should include the weight of any backfill acting on top of the foundation in addition to the weight of the foundation itself plus the applied load it is carrying.
Example 8.5

A continuous footing is 1.8 m wide by 0.5 m deep and is founded at a depth of 0.75 m in a clay soil of unit weight 20 kN/m³ with $\phi_u = 0^\circ$ and $c_u = 30$ kPa. The foundation is to carry a vertical line load of magnitude 50 kN/m run, which will act at a distance of 0.4 m from the centre-line. Take the unit weight of concrete as 24 kN/m³.

(i) Determine the safe bearing capacity for the footing, taking $F = 3.0$.

(ii) Check the Eurocode 7 GEO limit state (Design Approach 1) by establishing the magnitude of the over-design factor.

Solution

(i) Safe bearing capacity

Self-weight of foundation, $W_f = 0.5 \times 24 \times 1.8 = 21.6$ kN/m run

Weight of soil on top of foundation, $W_s = 0.25 \times 20 \times 1.8 = 9.0$ kN/m run

Total weight of foundation + soil, $W = 21.6 + 9.0 = 30.6$ kN/m run

Eccentricity of bearing pressure, $e = \frac{P \times e_p}{P + W} = \frac{50 \times 0.4}{50 + 30.6} = 0.25$ m

Since $e \leq \frac{B}{6}$, the total force acts within the middle third of the foundation.

Effective width of footing, $B' = 1.8 - 2 \times 0.25 = 1.3$ m

From Table 8.1, for $\phi_u = 0^\circ$, $N_c = 5.14$, $N_q = 1.0$, $N_y = 0$.

Footing is continuous, i.e. $L \rightarrow \infty$; $s_c = 1.0$.

$$d_c = 1 + 0.4 \left( \frac{0.75}{1.8} \right) = 1.17$$

Safe bearing capacity (per metre run) = $\frac{q_{u,net}}{3} + \gamma z = \frac{c_{u,net} s_c d_c}{3} + \gamma z$

= $30 \times 5.14 \times 1.0 \times 1.17 + 20 \times 0.75$

= 75 kPa

Safe bearing capacity = $75 \times B' = 97.5$ kN/m run

(ii) Eurocode 7 GEO limit state

1. Combination 1 (partial factor sets A1 + M1 + R1)

From Table 7.1: $\gamma_{G,\text{dst}} = 1.35$; $\gamma_{Q,\text{dst}} = 1.5$; $\gamma_{cu} = 1.0$; $\gamma_{kv} = 1.0$.

Design material property: $c_{u,\text{net}} = \frac{c_u}{\gamma_{cu}} = \frac{30}{1} = 30$ kPa
Design actions:

Weight of foundation, \( W_d = W \times \gamma_{G,dst} = 30.6 \times 1.35 = 41.3 \text{ kN/m run} \)
Applied line load, \( P_d = P \times \gamma_{G,dst} = 50 \times 1.35 = 67.5 \text{ kN/m run} \)

Effect of design actions:

Total vertical force, \( F_d = 41.3 + 67.5 = 108.8 \text{ kN/m run} \)

Eccentricity, \( e = \frac{P_d \times e_p}{P_d + W_d} = \frac{67.5 \times 0.4}{67.5 + 41.3} = 0.248 \text{ m} \)

Since \( e \leq \frac{B}{6} \), the total force acts within the middle-third of the foundation.

Effective width of footing, \( B' = 1.8 - 2 \times 0.248 = 1.3 \text{ m} \)

Design resistance:

From before, \( N_c = 5.14, N_q = 1.0, N_r = 0, s_c = 1.0 \).

Ultimate bearing capacity, \( q_u = c_{ud,d} N_c s_c + \gamma z N_q = 30 \times 5.14 \times 1 + 20 \times 0.75 \times 1.0 = 169.2 \text{ kPa} \)

Ultimate bearing capacity per metre run, \( Q_u = 169.2 \times 1.3 = 220 \text{ kN/m run} \)

Bearing resistance, \( R_d = \frac{Q_u}{\gamma_{Rv}} = \frac{220}{1} = 220 \text{ kN/m run} \)

Over-design factor, \( \Gamma = \frac{R_d}{F_d} = \frac{220}{108.8} = 2.03 \)

Since \( \Gamma > 1 \), the GEO limit state requirement is satisfied.

2. Combination 2 (partial factor sets \( A2 + M2 + R1 \))

The calculations are the same as for Combination 1 except that this time the following partial factors (from Table 7.1) are used: \( \gamma_{G,dst} = 1.0; \gamma_{Q,dst} = 1.3; \gamma_{cu} = 1.40; \gamma_{Rv} = 1.0 \).

\( c_{ud,d} = 21.4 \text{ kPa} \)
\( W_d = 30.6 \times 1.0 = 30.6 \text{ kN/m run} \)
\( P_d = 50.0 \times 1.35 = 50.0 \text{ kN/m run} \)
\( F_d = 30.6 + 50.0 = 80.6 \text{ kN/m run} \)
\( e = 0.248 \text{ m}; B' = 1.3 \text{ m} \)
\( Q_u = (c_{ud,d} N_c s_c + \gamma z N_q) \times B' = 125.1 \times 1.3 = 163.1 \text{ kN/m run} \)

\( R_d = \frac{Q_u}{\gamma_{Rv}} = \frac{163.1}{1} = 163.1 \text{ kN/m run} \)

\( \Gamma = \frac{R_d}{F_d} = \frac{163.1}{80.6} = 2.02 \)

Since \( \Gamma > 1 \), the GEO limit state requirement is satisfied.
Example 8.6

A concrete foundation 3 m wide, 9 m long and 0.75 m deep is to be founded at a depth of 1.5 m in a deep deposit of dense sand. The angle of shearing resistance of the sand is 35° and its unit weight is 19 kN/m³. The unit weight of concrete is 24 kN/m³.

(a) Using a lumped factor of safety approach (take \( F = 3.0 \)):

(i) Determine the safe bearing capacity for the foundation.

(ii) Determine the safe bearing capacity of the foundation if it is subjected to a vertical line load of 220 kN/m at an eccentricity of 0.3 m, together with a horizontal line load of 50 kN/m acting at the base of the foundation as illustrated in Figure 8.10.

(b) For the situation described in (ii) above, establish the magnitude of the over-design factor for the Eurocode 7 GEO limit state, using Design Approach 1.

Solution

(a) Lumped factor of safety

(i)

Safe bearing capacity

\[
\frac{q_{\text{net}}}{3} + \gamma z = \frac{\gamma z (N_q s_q d_q - 1)}{3} + 0.5 \gamma B N_r s_r d_r + \gamma z
\]

From Table 8.1, for \( \phi' = 35^\circ \), \( N_q = 33.3 \), \( N_r = 48.03 \):

\[
s_q = 1 + \left( \frac{3}{9} \right) \tan 35^\circ = 1.23; \quad s_r = 1 - 0.4 \left( \frac{3}{9} \right) = 0.87
\]

\[
d_q = 1 + 2 \tan 35^\circ (1 - \sin 35^\circ) \left( \frac{1.5}{3} \right) = 1.13; \quad d_r = 1
\]

Excel: SEOC08 28/04/2006 02:04PM Page 323
Safe bearing capacity

\[
= \frac{19 \times 1.5(33.3 \times 1.23 \times 1.13 - 1) + 0.5 \times 19 \times 3 \times 48.03 \times 0.87 \times 1.0}{3} + 19 \times 1.5
\]

\[= 855.7 \text{ kPa}\]

(ii)
Self-weight of foundation, \(W = 0.75 \times 9 \times 3 \times 24 = 486 \text{ kN}\)
Total applied vertical load, \(P = 220 \times 9 = 1980 \text{ kN}\)
Total applied horizontal load, \(H = 50 \times 9 = 450 \text{ kN}\)
Total vertical load acting on soil, \(V = 486 + 1980 = 2466 \text{ kN}\)

Eccentricity of bearing pressure

\[
e = \frac{P \times e_p}{P + W} = \frac{1980 \times 0.3}{2466} = 0.24 \text{ m}
\]

Since \(e \leq \frac{B}{6}\), the total force acts within the middle-third of the foundation.

Effective width of footing, \(B' = 3.0 - 2 \times 0.24 = 2.52 \text{ m}\)

The foundation is effectively acted upon by a load of magnitude, \(F\) inclined at an angle to the vertical, \(\alpha\):

\[
F = \sqrt{V^2 + H^2} = \sqrt{2466^2 + 450^2} = 2506.7 \text{ kN}
\]

\[
\alpha = \tan^{-1}\left(\frac{450}{2466}\right) = 10.3^\circ
\]

\[
i_q = \left(1 - \frac{10.3}{90}\right)^2 = 0.78; \quad i_{\gamma} = \left(1 - \frac{10.3}{35}\right)^2 = 0.50
\]

\[
s_q = 1 + \frac{2.52}{9} \tan 35^\circ = 1.2; \quad s_{\gamma} = 1 \times 0.4 \left(\frac{2.52}{9}\right) = 0.89
\]

\[
d_q = 1 + 2 \tan 35^\circ(1 - \sin 35^\circ)\left(\frac{1.5}{2.52}\right) = 1.15; \quad d_{\gamma} = 1
\]

Safe bearing capacity

\[
= \frac{\gamma z(N_q s_q d_q i_q - 1) + 0.5 \gamma B' N_{\gamma} s_{\gamma} d_{\gamma} i_{\gamma}}{3} + \gamma z
\]

\[
= \frac{19 \times 1.5(33.3 \times 1.2 \times 1.15 \times 0.78 - 1) + 0.5 \times 19 \times 2.52 \times 48.03 \times 0.89 \times 1.0 \times 0.5}{3}
\]

\[+ 19 \times 1.5
\]

\[= 530 \text{ kPa}\]
(b) Eurocode 7

Weight of soil on top of foundation, \( W_s = 0.75 \times 9 \times 3 \times 19 = 384.8 \text{ kN} \)
Total weight of foundation + soil, \( W = 486 + 384.8 = 870.8 \text{ kN} \)

1. Combination 1 (partial factor sets \( A1 + M1 + R1 \))

From Table 7.1: \( \gamma_{G,\text{dst}} = 1.35; \gamma_{Q,\text{dst}} = 1.5; \gamma_{\phi} = 1.0; \gamma_{Rv} = 1.0 \).

Design material property: \( \phi' = \tan^{-1} \left( \frac{\tan \phi'}{\gamma_{G,\text{dst}}} \right) = 35^\circ \)

Design actions:

- Weight of foundation, \( W_d = W \times \gamma_{G,\text{dst}} = 870.8 \times 1.35 = 1175.6 \text{ kN} \)
- Applied vertical line load, \( P_d = P \times \gamma_{G,\text{dst}} = 1980 \times 1.35 = 2673 \text{ kN} \)
- Applied horizontal line load, \( H_d = H \times \gamma_{G,\text{dst}} = 450 \times 1.35 = 607.5 \text{ kN} \)

Effect of design actions:

- Total vertical force, \( F_d = W_d + P_d = 1175.6 + 2673 = 3848.6 \text{ kN} \)
- Eccentricity, \( e = \frac{P_d \times e_p}{P_d + W_d} = \frac{2673 \times 0.3}{3848.6} = 0.208 \text{ m} \)

Since \( e \leq \frac{B}{6} \), the total force acts within the middle-third of the foundation.

- Effective width of footing, \( B' = 3.0 - 2 \times 0.208 = 2.58 \text{ m} \)
- Effective area of footing, \( A' = 2.58 \times 9 = 23.2 \text{ m}^2 \)

Design resistance:

From Table 8.1, \( N_c = 46.1, N_q = 33.3 \).

From Eurocode 7, Annex D,

\[
N_r = 2 (N_q - 1) \tan \phi' = 45.2
\]
\[
s_q = 1 + \frac{B'}{L} \sin \phi' = 1 + \left( \frac{2.58}{9} \right) \sin 35^\circ = 1.16
\]
\[
s_e = \frac{s_q - 1}{N_q - 1} = 1.17
\]
\[
s_r = 1 - 0.3 \left( \frac{B'}{L} \right) = 0.91
\]
\[
m = \frac{2 + \frac{B'}{L}}{1 + \frac{B'}{L}} = 1.78
\]
\[ i_q = \left[ 1 - \frac{H}{V + A'c' \cot \phi'} \right]^m = \left[ 1 - \frac{607.5}{3848.6 + 0} \right]^{1.78} = 0.74 \quad (V = F_q) \]

\[ i_c = \frac{1 - i_q}{N_c \tan \phi'} = 0.74 - \frac{1 - 0.74}{46.1 \tan 35^\circ} = 0.72 \]

\[ i_{\gamma} = \left( \frac{i_{\gamma}}{i_q} \right) = 0.74 \cdot \frac{1.14}{1.78} = 0.62 \]

Ultimate bearing capacity, per m²,

\[ q_u = c'd'N_c i_c + \gamma_d N_q i_q + 0.5B' \gamma_s N_s i_s \gamma \]

\[ = 0 + (19 \times 1.5 \times 33.3 \times 1.16 \times 0.74) \]

\[ + (0.5 \times 2.58 \times 19 \times 45.2 \times 0.91 \times 0.62) \]

\[ = 1439 \text{ kPa} \]

Ultimate bearing capacity, \( Q_u = q_u \times L \times B = 1439 \times 9 \times 3 = 38 \text{ 853 kN} \)

Bearing resistance, \( R_d = \frac{Q_u}{\gamma_{Rv}} = 38 \text{ 853} \text{ kN} \)

Over-design factor, \( \Gamma = \frac{R_d}{F_d} = \frac{38 \text{ 853}}{3848.6} = 10.1 \)

Since \( \Gamma > 1 \), the GEO limit state requirement is satisfied.

2. Combination 2 (partial factor sets \( A2 + M2 + R1 \))

The calculations are the same as for Combination 1 except that this time the following partial factors (from Table 7.1) are used: \( \gamma_{G,dst} = 1.0; \gamma_{Q,dst} = 1.3; \gamma'_{R} = 1.25; \gamma_{Rv} = 1.0. \)

\[ \phi' = \tan^{-1} \left( \frac{\tan \phi'}{\gamma_{G,dst}} \right) = \tan^{-1} \left( \frac{\tan 35^\circ}{1.25} \right) = 29.3^\circ \]

\[ W_d = 870.8 \times \gamma_0 = 870.8 \text{ kN} \]

\[ P_d = 1980 \times \gamma_0 = 1980 \text{ kN} \]

\[ H_d = 450 \times \gamma_0 = 450 \text{ kN} \]

\[ e = \frac{P_d \times \varepsilon_p}{P_d + W_d} = \frac{1980 \times 0.3}{1980 + 870.8} = 0.208 \text{ m} \quad \text{(within the middle-third)} \]

\[ B' = 3.0 - 2 \times 0.208 = 2.58 \text{ m} \]

\[ N_q = 16.9, N_{\gamma} = 17.8, s_q = 1.14, s_{\gamma} = 0.91, i_q = 0.74, i_{\gamma} = 0.62. \]

Ultimate bearing capacity, per m²,

\[ q_u = c'd'N_c i_c + \gamma_d N_q i_q + 0.5B' \gamma_s N_s i_s \gamma \]

\[ = 653.5 \text{ kPa} \]
8.8 Non-homogeneous soil conditions

The bearing capacity equations (6)–(10) are based on the assumption that the foundation soil is homogeneous and isotropic.

In the case of variable soil conditions the analysis of bearing capacity can be carried out using some form of slip circle method, as described earlier in this chapter. This procedure can take time and designs based on one of the bearing capacity formulae are consequently quite often used.

For the case of a foundation resting on thin layers of soil, of thicknesses $H_1, H_2, H_3, \ldots, H_n$ and of total depth $H$, Bowles (1982) suggests that these layers can be treated as one layer with an average $c$ value $c_{av}$ and an average $\phi$ value $\phi_{av}$, where

$$c_{av} = \frac{c_1 H_1 + c_2 H_2 + c_3 H_3 + \cdots + c_n H_n}{H}$$

$$\phi_{av} = \arctan \frac{H_1 \tan \phi_1 + H_2 \tan \phi_2 + H_3 \tan \phi_3 + \cdots + H_n \tan \phi_n}{H}$$

Vesic (1975) suggested that, for the case of a foundation founded in a layer of soft clay which overlies a stiff clay, the ultimate bearing capacity of the foundation can be expressed as:

$$q_u = c_u N_{cm} + \gamma z$$

where $c_u$ is the undrained strength of the soft clay and $N_{cm}$ is a modified form of $N_e$, the value of which depends upon the ratio of the $c_u$ values of both clays, the thickness of the upper layer, the foundation depth and the shape and width of the foundation. Values of $N_{cm}$ are quoted in Vesic’s paper.

The converse situation, i.e. that of a foundation founded in a layer of stiff clay which overlies a soft clay, has been studied by Brown and Meyerhof (1969), who quoted a formula for $N_{cm}$ based on a punching shear failure analysis.

For other cases of more heterogeneous soil conditions there is at present no recognised method by which the bearing capacity equations can be realistically applied.
At first glance a safe way of determining the bearing capacity of a foundation might be to base it on the shear strength of the weakest soil below it, but such a procedure can be uneconomical, particularly if the weak soil is overlain by much stronger soil. A more suitable method is to calculate the safe bearing capacity using the shear strength of the stronger material and then to check the amount of overstressing that this will cause in the weaker layers. The method is shown in Example 8.7, which illustrates a typical problem that may arise during the selection of a site for a new spoil heap.

For structural foundations the factor of safety against bearing capacity failure is generally not less than 3.0, but for spoil heaps this factor can often be reduced to 2.0.

**Example 8.7**

The effective width of a proposed spoil heap will be about 61 m. The subsoil conditions on which the tip is to be built are shown in Fig. 8.11a.

Determine a value for the maximum safe pressure that may be exerted by the tip on to the soil.

**Solution**

The average undrained cohesion of the stiff clay is about 165 kPa.

Using this value with Terzaghi’s formula:

\[ q_u = cN_c = 165 \times 5.7 = 940 \text{ kPa} \]

Assign safe bearing capacity = 430 kPa;\[ F = \frac{940}{430} = 2.19 \]

Various vertical sections through the soil must now be selected (A, B, C, D and E in Fig. 8.11a). Using a contact pressure value of 430 kPa, the induced shear stresses are obtained from Fig. 4.11b, and for each section the variation in soil strength with depth is plotted along with the corresponding values of shear stress increments (Fig. 8.11b). From these plots the areas of overstressing (shown hatched) are apparent and it is possible to plot this area on a cross-section (Fig. 8.11c).

A considerable portion of the silt is overstressed and if this were applied to the design of a raft foundation carrying a normal structure it would not be acceptable. With a spoil heap, however, the amount of settlement induced would hardly be detrimental. Also, as the load will be applied gradually, there will be a chance for the silt to consolidate partially and obtain some increase in strength before the full load is applied.

Owing to the thickness of boulder clay there is little chance of a heave of the ground surface around the tip. For interest, the overstressed zone corresponding to a contact pressure of 320 kPa is also shown in Fig. 8.11c.
If the contact pressure had been determined by considering the strength of the silt (average $c = 67$ kPa):

$$q_u = 5.7 \times 67 \text{ kPa} = 382 \text{ kPa}$$

Safe bearing capacity ($F = 2$) = 191 kPa
8.9 \textbf{In situ} testing for ultimate bearing capacity

8.9.1 The plate loading test

In this test an excavation is made to the expected foundation level of the proposed structure and a steel plate, usually from 300 to 750 mm square, is placed in position and loaded by means of a kentledge. During loading the settlement of the plate is measured and a curve similar to that illustrated in Fig. 8.12 is obtained.

On dense sands and gravels and stiff clays there is a pronounced departure from the straight line relationship that applies in the initial stages of loading, and the \(q_u\) value is then determined by extrapolating backwards (as shown in the figure). With a soft clay or a loose sand the plate experiences a more or less constant rate of settlement under load and no definite failure point can be established.

In spite of the fact that a plate loading test can only assess a metre or two of the soil layer below the test level, the method can be extremely helpful in stony soils where undisturbed sampling is not possible provided it is preceded by a boring programme, to prove that the soil does not exhibit significant variations.

The test can give erratic results in sands when there is a variation in density over the site, and several tests should be carried out to determine a sensible average. This procedure is costly, particularly if the groundwater level is near the foundation level and groundwater lowering techniques consequently become necessary.

\textbf{Estimation of allowable bearing pressure from the plate loading test}

As would be expected, the settlement of a square footing kept at a constant pressure increases as the size of the footing increases.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig812.png}
\caption{Typical plate loading test results.}
\end{figure}
Terzaghi and Peck (1948) investigated this effect and produced the relationship:

$$ S = S_1 \left( \frac{2B}{B + 0.3} \right)^2 $$

where

- $S_1$ = settlement of a loaded area 0.305 m square under a given loading intensity $p$
- $S$ = settlement of a square or rectangular footing of width $B$ (in metres) under the same pressure $p$.

In order to use plate loading test results the designer must first decide upon an acceptable value for the maximum allowable settlement. Unless there are other conditions to be taken into account it is generally accepted that maximum allowable settlement is 25 mm.

The method for determining the allowable bearing pressure for a foundation of width $B$ m is apparent from the formula. If $S$ is put equal to 25 mm and the numerical value of $B$ is inserted in the formula, $S_1$ will be obtained. From the plate loading test results we have the relationship between $S_1$ and $p$ (Fig. 8.12), so the value of $p$ corresponding to the calculated value of $S_1$ is the allowable bearing pressure of the foundation subject to any adjustment that may be necessary for certain groundwater conditions. The adjustment procedure is the same as that employed to obtain the allowable bearing pressure from the standard penetration test.

### 8.9.2 Standard penetration test

This test is generally used to determine the bearing capacity of sands or gravels and is conducted with a split spoon sampler (a sample tube which can be split open longitudinally after sampling) with internal and external diameters of 35 and 50 mm respectively. The sampler is sometimes referred to as the Raymond spoon sampler after the piling firm that evolved the test (Fig. 8.13). A full guide on the methods and use of the SPT is given by Clayton (1995).

![Standard penetration test](Fig. 8.13)
The sampler is lowered down the borehole until it rests on the layer of cohesionless soil to be tested. It is then driven into the soil for a length of 450 mm by means of a 65 kg hammer free-falling 760 mm for each blow. The number of blows required to drive the last 300 mm is recorded and this figure is designated as the N value of the soil (the first 150 mm of driving is ignored because of possible loose soil in the bottom of the borehole from the boring operations). After the tube has been removed from the borehole it can opened and its contents examined.

In gravelly soils damage can occur to the cutting head, and a solid cone, evolved by Palmer and Stuart (1957), is fitted in its place. The N value derived from such soils appears to be of the same order as that obtained when the cutting head is used in finer soils.

Terzaghi and Peck (1948) evolved a qualitative relationship between the relative density of the soil tested and the number of blows from the standard penetration test, N. Gibbs and Holtz (1957) put figures to this relationship, which are given in Table 8.2.

The sampler is lowered down the borehole until it rests on the layer of cohesionless soil to be tested. It is then driven into the soil for a length of 450 mm by means of a 65 kg hammer free-falling 760 mm for each blow. The number of blows required to drive the last 300 mm is recorded and this figure is designated as the N value of the soil (the first 150 mm of driving is ignored because of possible loose soil in the bottom of the borehole from the boring operations). After the tube has been removed from the borehole it can opened and its contents examined.

In gravelly soils damage can occur to the cutting head, and a solid cone, evolved by Palmer and Stuart (1957), is fitted in its place. The N value derived from such soils appears to be of the same order as that obtained when the cutting head is used in finer soils.

Terzaghi and Peck (1948) evolved a qualitative relationship between the relative density of the soil tested and the number of blows from the standard penetration test, N. Gibbs and Holtz (1957) put figures to this relationship, which are given in Table 8.2.

**Corrections to the measured N value**

An important feature of the standard penetration test is the influence of the effective overburden pressure on the N count. Sand can exhibit different N values at different depths even though its relative density is constant. Terzaghi and Peck make no reference to the effects that this can have, but Gibbs and Holtz examined the effects of most of the variables involved and concluded that the significant factors affecting the N value are the relative density of the soil and the value of the effective overburden pressure removed.

Various workers have investigated this problem (Coffmann, 1960; Bazaraa, 1967), but the method proposed by Thorburn (1963) now seems to have gained general acceptance, at least in the UK.

Thorburn assumed that the original Terzaghi and Peck relationships between N and the relative density corresponded to an effective overburden pressure of 138 kPa. His correction chart therefore dealt with a range of effective overburden pressure for 0 to 138 kPa, it being tacitly assumed that for values of effective overburden pressure greater than 138 kPa, N’ can be taken as equal to N.
It is possible, by the use of Thorburn’s chart, to prepare the plot of the $N'/N$ ratio relationship to effective overburden pressure, over the range 0 to 138 kPa (roughly from 0 to 7 m depth of overburden).

This relationship is reproduced in Fig. 8.14 and can be used directly in design.

Terzaghi and Peck point out that in saturated (i.e. below the water table) fine and silty sands the $N$ value can be altered by the low permeability of the soil. If the void ratio of the soil is higher than that corresponding to its critical density, the penetration resistance is less than in a large-grained soil of the same relative density. Conversely, if the void ratio is less than that corresponding to critical density the penetration resistance is increased.

The value of $N$ corresponding to the critical density appears to be about 15, and Terzaghi and Peck suggest that if the number of measured blows, $N$, is greater than 15 it should be assumed that the density of the tested soil is equal to that of a sand for which the number of blows is equal to $15 + 0.5 (N - 15)$, i.e.:

$$\text{True } N = 15 + 0.5 (N - 15)$$

where

$N =$ actual number of blows recorded in the test

True $N =$ number of blows from which $N'$ should be evaluated

_Estimation of allowable bearing pressure from the standard penetration test_

Having obtained $N'$, the determination of the allowable bearing pressure is generally based upon an empirical relationship evolved by Terzaghi and Peck (1948) that is based on the measured settlements of various foundations on sand (Fig. 8.15). The allowable bearing pressure for these curves (which are applicable to both square and rectangular foundations) was defined by Terzaghi and Peck as the pressure that will not cause a settlement greater than 25 mm.
When several foundations are involved the normal design procedure is to determine an average value for $N'$ from all the boreholes. The allowable bearing pressure for the widest foundation is then obtained with this figure and this bearing pressure is used for the design of all the foundations. The procedure generally leads to only small differential settlements, but even in extreme cases the differential settlement between any two foundations will not exceed 20 mm.

The curves of Fig. 8.15 apply to unsaturated soils, i.e. when the water table is at a depth of at least 1.0 $B$ below the foundation. When the soil is submerged the value of allowable bearing pressure obtained from the curves should be reduced. Originally the values were reduced to 50 per cent but this is now considered excessively conservative as the influence of the groundwater will have already been included in the observed penetration resistance. General practice is now to apply the 50 per cent reduction if the groundwater level is at or above the foundation level, and to apply no reduction if the groundwater level occurs at a depth of at least $B$ below the foundation level. Between these two limits the amount of reduction can be estimated by linear interpolation.

If settlement is of no consequence it is possible to think in terms of ultimate bearing capacity using the approximate relationship between $\phi'$ and $N'$ given in Fig. 3.34. Knowing $N'$, a $\phi'$ value, from which bearing capacity coefficients are evaluated, can be obtained. This procedure is not generally adopted.

![Fig. 8.15 Allowable bearing pressure from the standard penetration test (after Terzaghi and Peck, 1948).](image-url)
**Example 8.8**

A granular soil was subjected to standard penetration tests at depths of 3 m. Groundwater level occurred at a depth of 1.5 m below the surface of the soil which was saturated and had a unit weight of 19.3 kN/m³. The average N count was 15.

(i) Determine the corrected value $N'$.  
(ii) A strip footing, 3 m wide, is to be founded at a depth of 3 m. Assuming that the sand’s strength characteristics are constant with depth, determine the allowable bearing pressure.

**Solution**

(i) Effective overburden pressure $= 3 \times 19.3 - 1.5 \times 10 = 43$ kPa  
From Fig. 8.14, for $\sigma'_v = 43$ kPa, $N'/N = 2.1$.  
Therefore $N' = 15 \times 2.1 = 31$.

(ii) From Fig. 8.15, for $N' = 31$ and $B = 3$ m:  
Allowable bearing pressure $= 300$ kPa  
But this value is for *dry* soil and the sand below the foundation is also below groundwater level and is therefore submerged.  
It seems that allowable bearing pressure $= \frac{300}{2} = 150$ kPa

### 8.9.3 Correlation between the plate loading and the standard penetration tests

Meigh and Nixon (1961) compared the results of plate loading tests with those of standard penetration tests carried out at the same sites by determining from both sets of results the allowable bearing pressure, $p$ (defined as the pressure causing 25 mm settlement of the foundation) for a 3.05 m square foundation. The differences were quite marked: for fine and silty sands the plate loading test led to values of $p$ about 1.5 times the value obtained from the standard penetration test results, whilst for gravels the plate loading test gave values of $p$ that were from 4 to 6 times greater.

It should be pointed out that Meigh and Nixon used the uncorrected N test values in their calculations, and when Sutherland (1963) examined Meigh and Nixon’s results he showed that the disparity between the allowable bearing pressures calculated from the two tests became much less when the corrected $N'$ value (in which overburden pressure is allowed for) was used.
8.9.4 *The static cone penetration test*

This penetrometer, often called the Dutch cone penetrometer, is headed by a cone of overall diameter 35.7 mm, giving an end area of 1000 mm², and having an apex angle of 60°. The cone is forced downwards at a steady rate (15–20 mm/s) through the soil by means of a load from a hydraulic cylinder transmitted to solid 15 mm diameter rods. These solid rods are centrally placed within 36 mm diameter outer rods. The load acting at the top of the inner rods can be determined from pressure gauge readings and the cone resistance, \( C_r \), is taken to be this load divided by the end area.

Improved forms of the Dutch cone, such as that introduced by Begemann (1965), make it possible to measure cone and side resistances separately, an advantage if the test results are to be used in pile design.

A further development has been the electrical friction–cone penetrometer, described by Lousberg *et al.* (1974), in which the cone penetration resistance is measured and recorded continuously by means of a load cell within the instrument. The penetrometer also has a frictional sleeve connected to a second and independent load cell so that frictional resistance can also be recorded.

A full description of cone penetration testing and its application in geotechnical and geo-environmental engineering is given by Lunne *et al.* (1997).

8.9.5 *Presumed bearing capacity*

The British Standard BS 8004: 1986 gives a list of safe bearing capacity values and this is reproduced in Table 8.3. The values are based on the following assumptions:

(i) The site and adjoining sites are reasonably level.
(ii) The ground strata are reasonably level.
(iii) There is no softer layer below the foundation stratum.
(iv) The site is protected from deterioration.

Foundations designed to these values will normally have an adequate factor of safety against bearing capacity failure, provided that they are not subjected to inclined loading, but it must be remembered that settlement effects have not been considered.

For cohesive soils the consistency is related to the undrained strength, \( c_u \). Such a relationship is suggested in BS 5930 and is reproduced in Table 8.4.
8.10 Pile foundations

The use of sheet piling, which can be of timber, concrete or steel, for earth retaining structures has been described in Chapter 7. Piled foundations form a separate category and are generally used:

---
(i) to transmit a foundation load to a solid soil stratum;
(ii) to support a foundation by friction of the piles against the soil;
(iii) to resist a horizontal or uplift load;
(iv) to compact a loose layer of granular soil.

8.10.1 Classification of piles

Piles can be classified by different criteria, such as their material (e.g. concrete, steel, timber), their method of installation (e.g. driven or bored), the degree of soil displacement during installation, or their size (e.g. large diameter, small diameter). However, in terms of pile design, the most appropriate classification criteria is the behaviour of the pile once installed (e.g. end bearing pile, friction pile, combination pile).

End bearing (Fig. 8.16a)

Derive most of their carrying capacity from the penetration resistance of the soil at the toe of the pile. The pile behaves as an ordinary column and should be designed as such except that, even in weak soil, a pile will not fail by buckling and this effect need only be considered if part of the pile is unsupported, i.e. it is in either air or water.

Friction (Fig. 8.16b)

Carrying capacity is derived mainly from the adhesion or friction of the soil in contact with the shaft of the pile.

Combination (Fig. 8.16c)

Really an extension of the end bearing pile when the bearing stratum is not hard, such as a firm clay. The pile is driven far enough into the lower material to develop adequate frictional resistance. A further variation of the end bearing pile is piles with enlarged bearing areas. This is achieved by forcing a bulb of concrete into the soft stratum immediately above the firm layer to give an enlarged base. A similar effect is

Fig. 8.16 Classification of piles.
produced with bored piles by forming a large cone or bell at the bottom with a special reaming tool.

8.10.2 Driven piles

These are prefabricated piles that are installed into the ground through the use of a pile driver as illustrated in Fig. 8.17. The pile is hoisted into position on the pile driver and aligned against the runners so that the pile is driven into the ground at exactly the required angle, to exactly the required depth. The pile is driven into the soil by striking the top of the pile repeatedly with a pneumatic or percussive hammer or by driving the pile down using a hydraulic ram. Most commonly the piles are made from precast concrete although timber and steel piles are also available.

Precast concrete

These are usually of square or octagonal section. Reinforcement is necessary within the pile to help withstand both handling and driving stresses. Prestressed concrete piles are also used and are becoming more popular than ordinary precast as less reinforcement is required.

Timber

Timber piles have been used from earliest recorded times and are still used for permanent work where timber is plentiful. In the UK, timber piles are used mainly in temporary works, due to their lightness and shock resistance, but they are also used for piers and fenders and can have a useful life of some 25 years or more if kept
completely below the water table. However, they can deteriorate rapidly if used in ground in which the water level varies and allows the upper part to come above the water surface. Pressure creosoting is the usual method of protection. In tropical climes timber piles above groundwater level are liable to be destroyed by wood-eating insects, sometimes in a matter of weeks.

**Steel piles: tubular, box or H-section**

These are suitable for handling and driving in long lengths. They have a relatively small cross-sectional area and penetration is easier than with other types. The risk from corrosion is not as great as one might think although tar coating or cathodic protection can be employed in permanent work.

**Jetted pile**

When driving piles in non-cohesive soils the penetration resistance can often be considerably reduced by jetting a stream of high-pressured water into the soil just below the pile. There have been cases where piles have been installed by jetting alone. The method requires considerable experience, particularly when near to existing foundations.

**Vibrated pile**

As an alternative to jetting, vibration techniques can be used to place piles in granular soils. Vibrators are not efficient in clays but can be used if piles are to be extracted.

**Jacked pile**

Generally built up with a series of short sections of precast concrete, this pile is jacked into the ground and progressively increased in length by the addition of a pile section whenever space becomes available. The jacking force is easily measured and the load to pile penetration relationship can be obtained as jacking proceeds. Jacked piles are often used to underpin existing structures where lack of space excludes the use of pile driving hammers.

**Screw pile**

A screw pile consists of a steel, or concrete, cylinder with helical blades attached to its lower end. The pile is made to screw down into the soil by rotating the cylinder with a capstan at the top of the pile. A screw pile, due to the large size of its screw blades, can offer large uplift resistance.

### 8.10.3 Driven and cast-in-place piles

Two of the main types of this pile, used in Britain, are described below.
West’s shell pile

Precast, reinforced concrete tubes, about 1 m long, are threaded on to a steel mandrel and driven into the ground after a concrete shoe has been placed at the front of the shells. Once the shells have been driven to specification the mandrel is withdrawn and reinforced concrete inserted in the core. Diameters vary from 325 to 600 mm. Details of the pile and the method of installation are shown in Fig. 8.18.

Franki pile

A steel tube is erected vertically over the place where the pile is to be driven, and about a metre depth of gravel is placed at the end of the tube. A drop hammer, 1500 to 4000 kg mass, compacts the aggregate into a solid plug which then penetrates the soil and takes the steel tube down with it. When the required set has been achieved the tube is raised slightly and the aggregate broken out. Dry concrete is now added and hammered until a bulb is formed. Reinforcement is placed in position and more dry concrete is placed and rammed until the pile top comes up to ground level. The sequence of operations is illustrated in Fig. 8.19.

8.10.4 Bored and cast-in-situ piles

These piles are formed within a drilled borehole. During the drilling process the sides of the borehole are supported to prevent the soil from collapsing inwards and temporary sections of steel cylindrical casing are advanced along with the drilling process to provide this required support. As the drilling progresses, the soil is removed from within the casing and brought to the surface. Once the full depth of the borehole has been reached, the casing is gradually withdrawn, the reinforcement cage is placed...
and the concrete which forms the pile is pumped into the borehole. For very deep boreholes the installation of many sections of temporary casing can be an expensive and slow process, and an alternative means of supporting the sides is through the use of a bentonite slurry in the same manner as for a diaphragm wall (see Section 7.3.2).

An alternative technique which does not use borehole side-support is the continuous flight auger (CFA) pile. With this technique a continuous flight auger with a hollow stem is used to create the borehole. The sides of the borehole are supported by the soil on the flights of the auger and so no casing is required. Once the required depth has been reached, the concrete is pumped down the hollow stem and the auger is steadily withdrawn. The steel reinforcement is placed once the auger is clear of the borehole.

8.10.5 Large diameter bored piles

The driven or bored and cast-in-place piles discussed previously generally have maximum diameters in the order of 0.6 m and are capable of working loads round about 2 MN. With modern buildings column loads in the order of 20 MN are not uncommon. A column carrying such a load would need about ten conventional piles, placed in a group and capped by a concrete slab, probably some 25 m² in area.

A consequence of this problem has been the increasing use of the large diameter bored pile. This pile has a minimum shaft diameter of 0.75 m and may be underreamed to give a larger bearing area if necessary. Such a pile is capable of working loads in the order of 25 MN and, if taken down through the soft to the hard material, will minimise settlement problems so that only one such pile is required to support each column of the building. Large diameter bored piles have been installed in depths down to 60 m.

8.10.6 Determination of the bearing capacity of a pile by load tests

The load test is the only really reliable means of determining a pile’s load capacity, but it is expensive, particularly if the ground is variable and a large number of piles must therefore be tested.
Full-scale piles should be used—and these should be driven in the same manner as those placed for the permanent work.

Figure 8.20 gives rough indications of how a test pile may be loaded. A large mass of dead weight is placed on a platform supported by the pile. The load is applied in increments and the settlement is recorded when the rate of settlement has reduced to 0.25 mm in an hour, at which stage a further increment can be applied (Fig. 8.20a). The method has the disadvantage that the platform must be balanced on top of the pile and there is always the risk of collapse. An alternative, and better, technique is to jack the pile against a kentledge using an arrangement similar to Fig. 8.20b.

Sometimes the piles to be used permanently can be used to test a pile as shown in Fig. 8.20c.

The form of load to settlement relationship obtained from a loading test is shown in Fig. 8.20d. Loading is continued until failure occurs, except for large diameter bored piles which, having a working load of some 25 MN, would require massive kentledges if failure loads were to be achieved. General practice has become to test load these piles to the working load plus 50 per cent.

Design standards offer some limited guidance on static load pile test methods. BS 8004 specifies two types of test, described below, from which the ultimate load of a pile can be obtained, and Eurocode 7 (see Section 8.11) makes reference to the ASTM suggested method for the axial pile loading test, described by Smoltczyk (1985). Furthermore, it is likely that the forthcoming European standard for pile testing will adopt the recommendations and procedures described by De Cock et al. (2003).

(1) The maintained load test
Here the load is applied to the pile in a series of increments, usually equal to 25 per cent of the designated working load for the pile. The ultimate pile load is taken to be the load that achieves some specified amount of settlement, usually 10 per cent of the pile’s diameter.
The constant rate of penetration test
In this test the pile is jacked downwards at a constant rate of penetration. The ultimate pile load is considered to be the load at which either a shear failure takes place within the soil or the penetration of the pile equals 10 per cent of its diameter.

The figure of one tenth is intended for normal sized piles and, if applied to large diameter bored piles, could lead to excessive settlements if a factor of safety of 2.5 were adopted. This, of course, only applies to large diameter piles resting on soft rocks. In the case of a large diameter bored pile resting on hard rock the ultimate load depends upon the ultimate stress in the concrete.

8.10.7 Determination of the bearing capacity of a pile by soil mechanics

A pile is supported in the soil by the resistance of the toe to further penetration plus the frictional or adhesive forces along its embedded length.

Ultimate bearing capacity = Ultimate base resistance + Ultimate skin friction:

\[ Q_u = Q_b + Q_s \]

Cohesive soils

\[ Q_b \] for piles in cohesive soils is based on Meyerhof's equation (1951):

\[ Q_b = N_c \times c_b \times A_b \]

where

\[ N_c = \text{bearing capacity factor, widely accepted as equal to 9.0} \]
\[ c_b = \text{undisturbed undrained shear strength of the soil at base of pile}. \]

\[ Q_s \] is given by the equation:

\[ Q_s = \alpha \times c_u \times A_s \]

where

\[ \alpha = \text{adhesion factor} \]
\[ c_u = \text{average undisturbed undrained shear strength of soil adjoining pile} \]
\[ A_s = \text{surface area of embedded length of pile}. \]

Hence

\[ Q_u = c_b N_c A_b + \alpha c_u A_s \]
The adhesion factor $\alpha$

Most of the bearing capacity of a pile in cohesive soil is derived from its shaft resistance, and the problem of determining the ultimate load resolves into determining a value for $\alpha$. For soft clays $\alpha$ can be equal to or greater than 1.0 as, after driving, soft clays tend to increase in strength. In overconsolidated clays $\alpha$ has been found to vary from 0.3 to 0.6. The usual value assumed for London clay was, for many years, taken as 0.45 but more recently a value of 0.6 for this type of soil has become more accepted.

Cohesionless soils

The ultimate load of a pile installed in cohesionless soil is estimated using only the value of the drained parameter, $\phi'$, and assuming that any contribution due to $c'$ is zero.

$$Q_b = q_b A_b = \sigma'_v N_q A_b$$

where

$\sigma'_v = $ the effective overburden pressure at the base of the pile

$N_q = $ the bearing capacity coefficient

$A_b = $ the area of the pile base.

The selection of a suitable value for $N_q$ is obviously a crucial part of the design of the pile. The values suggested by Berezantzev et al. (1961) are often used and are reproduced in Fig. 8.21. Note that the full value of $N_q$ is used as it is assumed that the weight of soil removed or displaced is equal to the weight of the pile that replaced it.

![Fig. 8.21 Bearing capacity factor $N_q$ (after Berezantzev et al., 1961).](image-url)
\[ Q_s = f_s A_s \]

where

\[ f_s = \text{average value of the ultimate skin friction over the embedded length of the pile} \]
\[ A_s = \text{surface area of embedded length of pile} \]

Meyerhof (1959) suggested that for the average value of the ultimate skin friction:

\[ f_s = K_s \bar{\sigma}_v \tan \delta \]

where

\[ K_s = \text{the coefficient of lateral earth pressure} \]
\[ \bar{\sigma}_v = \text{average effective overburden pressure acting along the embedded length of the pile shaft} \]
\[ \delta = \text{angle of friction between the pile and the soil} \]

Hence

\[ Q_s = A_s K_s \bar{\sigma}_v \tan \delta \]

and

\[ Q_u = \sigma_v' N_d A_b + A_s K_s \bar{\sigma}_v \tan \delta \]

Typical values for \( \delta \) and \( K_s \) were derived by Broms (1966), and are listed in Table 8.5.

Vesic (1973) pointed out that the value of \( q_b \), i.e. \( \sigma_v' N_d \), does not increase indefinitely but has a limiting value at a depth of some 20 times the pile diameter. There is therefore a maximum value of \( \sigma_v' N_d \) that can be used in the calculations for \( Q_b \).

In a similar manner there is a limiting value that can be used for the average ultimate skin friction, \( f_s \). This maximum value of \( f_s \) occurs when the pile has an embedded...

length between 10 and 20 pile diameters. Vesic (1970) suggested that the maximum value of the average ultimate skin resistance should be obtained from the formula:

\[ f_s = 0.08(10)^{1.5(D_r)^i} \]

where \( D_r \) = the relative density of the cohesionless soil.

In practice \( f_s \) is often taken as 100 kPa if the formula gives a greater value.

Unlike piles embedded in cohesive soils, the end resistances of piles in cohesionless soils are of considerable significance and short piles are therefore more efficient in cohesionless soils.

### 8.10.8 Determination of soil piling parameters from in situ tests

With cohesionless soils it is possible to make reasonable estimates of the values of \( q_b \) and \( f_s \) from in situ penetration tests. Meyerhof (1976) suggests the following formulae to be used in conjunction with the standard penetration test.

**Driven piles**

- Sands and gravel \( q_b \approx \frac{40ND}{B} \leq 400 \text{N (kPa)} \)
- Non-plastic silts \( q_b \approx \frac{40ND}{B} \leq 300 \text{N (kPa)} \)

**Bored piles**

- Any type of granular soil \( q_b \approx \frac{14ND}{B} \text{ kPa} \)
- Large diameter driven piles \( f_s = 2\bar{N} \text{ kPa} \)
- Average diameter driven piles \( f_s = \bar{N} \text{ kPa} \)
- Bored piles \( f_s = 0.67\bar{N} \text{ kPa} \)

where

\( N \) = the uncorrected blow count at the pile base
\( \bar{N} \) = the average uncorrected \( N \) value over the embedded length of the pile
\( D \) = embedded length of the pile in the end bearing stratum
\( B \) = width, or diameter, of pile.

An alternative method is to use the results of the Dutch cone test. Typical results from such a test are shown in Fig. 8.22 and are given in the form of a plot showing the variation of the cone penetrations resistance with depth.

For the ultimate base resistance, \( C_r \), the cone resistance is taken as being the average value of \( C_r \) over the depth-4d as shown, where \( d = \) diameter of shaft. Then:

\[ Q_b = C_r A_b \]
Fig. 8.22  Typical results from a Dutch cone test.

The ultimate skin friction, $f_s$, can be obtained from one of the following:

$$f_s = \frac{C_r}{200} \text{ kPa} \quad \text{for driven piles in dense sand}$$

$$f_s = \frac{C_r}{400} \text{ kPa} \quad \text{for driven piles in loose sand}$$

$$f_s = \frac{C_r}{150} \text{ kPa} \quad \text{for driven piles in non-plastic silts}$$

where $C_r$ = average cone resistance along the embedded length of the pile (De Beer, 1963).

Then $Q_s = f_s A_s$ and, as before, $Q_u = Q_b + Q_s$.

**Example 8.9**

A 5 m thick layer of medium sand overlies a deep deposit of dense gravel. A series of standard penetration tests carried out through the depth of the sand has established that the average blow count, $N$, is 22. Further tests show that the gravel has a standard penetration value of $N = 40$ in the region of the interface with the sand. A precast pile of square section $0.25 \times 0.25$ m$^2$ is to be driven down through the sand and to penetrate sufficiently into the gravel to give good end bearing.

Adopting a safety factor of 3.0 determine the allowable load that the pile will be able to carry.
Solution

Ultimate bearing capacity of the pile = $Q_u = Q_s + Q_b$

$Q_b$: All end bearing effects will occur in the gravel. Now

$q_b = 40 \times 40 \times \frac{D}{0.25} = 400 \times 40 = 16000 \text{ kPa}$

Penetration into gravel, $D = \frac{16000 \times 0.25}{40 \times 40} = 2.5 \text{ m}$

and

$Q_b = 16000 \times 0.25^2 = 1000 \text{ kN}$

$Q_s$ in sand: $Q_s = f_s A_s = 22 \times 5 \times 0.25 \times 4 = 110 \text{ kN}$

$Q_s$ in gravel: $Q_s = f_s A_s = 40 \times 2.5 \times 0.25 \times 4 = 100 \text{ kN}$

$i.e.$

$Q_u = 210 + 1000 = 1210 \text{ kN}$

Allowable load $= \frac{1210}{3} = 400 \text{ kN}$

Example 8.9 illustrates that, as discussed earlier, the end bearing effects are much greater than those due to side friction. It can be argued that, in order to develop side friction (shaft resistance) fully, a significant downward movement of the pile is required which cannot occur in this example because of the end resistance of the gravel. As a result of this phenomenon, it is common practice to apply a different factor of safety to the shaft resistance than that applied to the end bearing resistance. Typically a factor of safety of around 1.5 is applied to shaft resistance, and a factor of safety between 2.5 and 3.0 is applied to the end bearing resistance.

Returning to Example 8.9, and adopting $F_b = 3$, $F_s = 1.5$, the allowable load now becomes:

$\frac{1000}{3} + \frac{210}{1.5} = 473 \text{ kN}$
Negative skin friction

If a soil subsides or consolidates around a group of piles these piles will tend to support the soil and there can be a considerable increase in the load on the piles.

The main causes for this state of affairs are that:

(i) bearing piles have been driven into recently placed fill;
(ii) fill has been placed around the piles after driving.

If negative friction effects are likely to occur then the piles must be designed to carry the additional load. In extreme cases the value of negative skin friction can equal the positive skin friction but, of course, this maximum value cannot act over the entire bedded length of the pile, being virtually zero at the top of the pile and reaching some maximum value at its base.

8.11 Designing pile foundations to Eurocode 7

The principles of Eurocode 7, as described in Section 7.4.2, apply to the design of pile foundations, and the reader is advised to refer back to that section whilst studying the following few pages.

The design of pile foundations is covered in Section 7 of Eurocode 7. There are 11 limit states listed that should be considered, though only those limit states most relevant to the particular situation would normally be considered in the design. These include the loss of overall stability, bearing resistance failure of the pile, uplift of the pile and structural failure of the pile. In this chapter we will look only at checking against ground resistance failure through the compressive loading of the pile.

Pile design methods acceptable to Eurocode 7 are in the main based on the results of static pile load tests, and the design calculations should be validated against the test results. When considering the compressive ground resistance limit state the task is to demonstrate that the design axial compression load on a pile or pile group, $F_{c,d}$, is less than or equal to the design compressive ground resistance, $R_{c,d}$, against the pile or pile group. In the case of pile groups, $R_{c,d}$ is taken as the lesser value of the design ground resistance of an individual pile and that of the whole group.

In keeping with the rules of Eurocode 7, the design value of the compressive resistance of the ground is obtained by dividing the characteristic value by a partial factor of safety. The characteristic value is obtained by one of three approaches: from static load tests, from ground tests results or from dynamic tests results.

(i) Ultimate compressive resistance from static load tests

The characteristic value of the compressive ground resistance, $R_{c,k}$, is obtained by combining the measured value from the pile load tests with a correlation factor, $\xi$ (related to the number of piles tested). More explicitly, $R_{c,k}$ is taken as the lesser value of:

$$R_{c,k} = \frac{(R_{cm})_{\text{mean}}}{\xi_1} \quad \text{and} \quad R_{c,k} = \frac{(R_{cm})_{\text{min}}}{\xi_2}$$
It may be that the characteristic compressive resistance of the ground is more appropriately determined from the characteristic values of the base resistance, $R_{b;k}$ and the shaft resistance, $R_{s;k}$:

$$R_{c;k} = R_{b;k} + R_{s;k}$$

The design compressive resistance of the ground may be derived by either:

$$R_{c;d} = \frac{R_{ck}}{\gamma_b}$$

or

$$R_{c;d} = \frac{R_{bk}}{\gamma_b} + \frac{R_{ck}}{\gamma_s}$$

where $\gamma_b$, $\gamma_s$ and $\gamma_t$ are partial factors on base resistance, shaft resistance and the total resistance respectively. The partial factors for piles in compression recommended in Eurocode 7 are given in Table 8.7.

Considering Design Approach 1, the following partial factor sets (see Section 7.4.2) are used for the design of axially loaded piles:

Combination 1: $A1 + M1 + R1$
Combination 2: $A2 + (M1 \text{ or } M2)^* + R4$

* $M1$ is used for calculating pile resistance; $M2$ is used for calculating unfavourable actions on piles.

where

$$(R_{cm})_{\text{mean}} = \text{the mean measured resistance}$$

$$(R_{cm})_{\text{min}} = \text{the minimum measured resistance}$$

$\xi_1$, $\xi_2 = \text{correlation factors obtained from Table 8.6.}$

**Table 8.6** Correlation factors – static load tests results.

From an understanding of the ground conditions, it is assumed that the ratio of base resistance to shaft resistance is 3:1.

Determine the design compressive resistance of the ground in accordance with Eurocode 7, Design Approach 1.

Solution

$$(R_{cm})_{mean} = \frac{382 + 425 + 365 + 412}{4} = 396 \text{ kN}$$

$$(R_{cm})_{min} = 365 \text{ kN}$$

From Table 8.6, $\xi_1 = 1.1$; $\xi_2 = 1.0$

$$R_{ck} = \frac{(R_{cm})_{mean}}{\xi_1} = \frac{396}{1.1} = 360 \text{ kN}$$

$$R_{ck} = \frac{(R_{cm})_{min}}{\xi_2} = \frac{365}{1.0} = 365 \text{ kN}$$

that is

$R_{ck} = 360 \text{ kN}$ (i.e. the minimum value)

Since the ratio of base resistance to shaft resistance is 3:1, we have:

- Characteristic base resistance, $R_{b,k} = 360 \times 0.75 = 270 \text{ kN}$
- Characteristic shaft resistance, $R_{s,k} = 360 \times 0.25 = 90 \text{ kN}$
1. Design Approach 1, Combination 1

Partial factor set R1 is used:

\[ R_{c,d} = \frac{R_{c,k}}{\gamma_t} = \frac{360}{1.15} = 313 \text{ kN} \]

or

\[ R_{c,d} = \frac{R_{b,k}}{\gamma_b} + \frac{R_{s,k}}{\gamma_s} = \frac{270}{1.25} + \frac{90}{1.0} = 306 \text{ kN} \]

2. Design Approach 1, Combination 2

Partial factor set R4 is used:

\[ R_{c,d} = \frac{R_{c,k}}{\gamma_t} = \frac{360}{1.5} = 240 \text{ kN} \]

or

\[ R_{c,d} = \frac{R_{b,k}}{\gamma_b} + \frac{R_{s,k}}{\gamma_s} = \frac{270}{1.6} + \frac{90}{1.3} = 238 \text{ kN} \]

The design compressive resistance of the ground is thus determined:

\[ R_{c,d} = \min(313, 306, 240, 238) = 238 \text{ kN} \]

(ii) Ultimate compressive resistance from ground tests results

The design compressive resistance can be determined from ground tests results. Here the characteristic compressive resistance, \( R_{c,k} \), is taken as the lesser value of:

\[ R_{c,k} = \frac{(R_{b,cal} + R_{s,cal})_{\text{mean}}}{\xi_3} \quad \text{and} \quad R_{c,k} = \frac{(R_{b,cal} + R_{s,cal})_{\text{min}}}{\xi_4} \]

where

\( (R_{b,cal})_{\text{mean}} \) = the mean calculated base resistance
\( (R_{s,cal})_{\text{mean}} \) = the mean calculated shaft resistance
\( (R_{b,cal})_{\text{min}} \) = the minimum calculated base resistance
\( (R_{s,cal})_{\text{min}} \) = the minimum calculated shaft resistance
\( \xi_3, \xi_4 \) = correlation factors obtained from Table 8.8.

The calculated base and shaft resistances are determined using the equations set out in Section 8.10.7.
Example 8.11

A 10 m long by 0.7 m diameter CFA pile is to be founded in a uniform soft clay. The following test results were established in a geotechnical laboratory as part of a site investigation:

<table>
<thead>
<tr>
<th>Borehole no.</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mean undrained strength along shaft, $c_{u,shaft}$ (kPa)</td>
<td>65</td>
<td>62</td>
<td>70</td>
<td>73</td>
</tr>
<tr>
<td>Mean undrained strength at base, $c_{u,base}$ (kPa)</td>
<td>90</td>
<td>79</td>
<td>96</td>
<td>100</td>
</tr>
</tbody>
</table>

The pile will carry a permanent axial load of 500 kN (includes the self-weight of the pile) and an applied transient (variable) axial load of 150 kN.

Check the bearing resistance (GEO) limit state in accordance with Eurocode 7, Design Approach 1 by establishing the magnitude of the over-design factor. Assume $N_c = 9$ and $\alpha = 0.7$.

Solution

Area of base of pile, $A_b = \frac{\pi D^2}{4} = \frac{\pi \times 0.7^2}{4} = 0.385 \text{ m}^2$

The total resistance is determined from the results from each borehole:

$$(R_{b,cal})_1 = (N_c \times c_{u,shaft} \times A_b) + (\pi \times D \times L \times \alpha \times c_{u,base}) = (9 \times 90 \times 0.385) + (\pi \times 0.7 \times 10 \times 0.7 \times 65) = 1312 \text{ kN}$$

$$(R_{b,cal})_2 = (9 \times 79 \times 0.385) + (\pi \times 0.7 \times 10 \times 0.7 \times 62) = 1228 \text{ kN}$$

$$(R_{b,cal})_3 = (9 \times 96 \times 0.385) + (\pi \times 0.7 \times 10 \times 0.7 \times 70) = 1410 \text{ kN}$$

$$(R_{b,cal})_4 = (9 \times 100 \times 0.385) + (\pi \times 0.7 \times 10 \times 0.7 \times 73) = 1470 \text{ kN}$$

$$(R_{c,cal})_{\text{mean}} = \frac{1312 + 1228 + 1410 + 1470}{4} = 1355 \text{ kN}$$

$$(R_{c,cal})_{\text{min}} = 1228 \text{ kN} \quad \text{(i.e. Borehole 2)}$$
From Table 8.8, $\xi_3 = 1.31$; $\xi_4 = 1.2$.

\[
R_{ck} = \frac{(R_{c,\text{cal}})_{\text{mean}}}{\xi_3} = \frac{1355}{1.31} = 1034 \text{ kN}
\]

\[
R_{ck} = \frac{(R_{c,\text{cal}})_{\text{min}}}{\xi_4} = \frac{1228}{1.2} = 1023 \text{ kN}
\]

that is, $(R_{c,\text{cal}})_{\text{min}}$ governs and this lower value of $R_{ck}$ is taken as the characteristic compressive resistance.

Therefore, using $\xi_4$:

- Characteristic base resistance, $R_{b,ck} = \frac{9 \times 79 \times 0.385}{1.20} = 228 \text{ kN}$
- Characteristic shaft resistance, $R_{s,ck} = \frac{\pi \times 0.7 \times 10 \times 0.7 \times 62}{1.20} = 795 \text{ kN}$

1. Design Approach 1, Combination 1:
   - Design resistance: partial factor set R1 is used (Table 8.7):
     
     \[
     R_{c,d} = \frac{R_{b,ck}}{\gamma_b} + \frac{R_{s,ck}}{\gamma_s} = \frac{228}{1.1} + \frac{795}{1.0} = 1002 \text{ kN}
     \]
   - Design actions: partial factor set A1 is used (Table 7.1):
     
     \[
     F_{c,d} = 500 \times 1.35 + 150 \times 1.5 = 900 \text{ kN}
     \]
   - Over-design factor, $\Gamma = \frac{1002}{900} = 1.11$

2. Design Approach 1, Combination 2:
   - Design resistance: partial factor set R4 is used (Table 8.7):
     
     \[
     R_{c,d} = \frac{R_{b,ck}}{\gamma_b} + \frac{R_{s,ck}}{\gamma_s} = \frac{228}{1.45} + \frac{795}{1.3} = 769 \text{ kN}
     \]
   - Design actions: partial factor set A2 is used (Table 7.1):
     
     \[
     F_{c,d} = 500 \times 1.0 + 150 \times 1.3 = 695 \text{ kN}
     \]
   - Over-design factor, $\Gamma = \frac{769}{695} = 1.11$

Since $\Gamma \geq 1$, the design of the pile satisfies the GEO limit state requirement.
(iii) Ultimate compressive resistance from dynamic tests results

Although static load tests and ground tests are the most common methods of determining the compressive resistance of the pile, the resistance can also be estimated from dynamic tests provided that the test procedure has been calibrated against static load tests.

8.12 Pile groups

8.12.1 Action of pile groups

Piles are usually driven in groups (see Fig. 8.23). In the case of end bearing piles the pressure bulbs of the individual piles will overlap (if spacing $< 5d$ – the usual condition). Provided that the bearing strata are firm throughout the affected depth of this combined bulb then the bearing capacity of the group will be equal to the summation of the individual strengths of the piles. However, if there is a compressible soil layer beneath the firm layer in which the piles are founded, care must be taken to ensure that this weaker layer is not overstressed.

Pile groups in cohesionless soils

Pile driving in sands and gravels compacts the soil between the piles. This compactive effect can make the bearing capacity of the pile group greater than the sum of the individual pile strengths. Spacing of piles is usually from two to three times the diameter, or breadth, of the piles.

Pile groups in cohesive soils

A pile group placed in a cohesive soil has a collective strength which is considerably less than the summation of the individual pile strengths which compose it. One characteristic of pile groups in cohesive soils is the phenomenon of ‘block failure’. If the piles are placed very close together (a common temptation when

Fig. 8.23 A typical pile group.
dealing with a limited site area), the strength of the groups may be governed by its
strength at block failure. This is when the soil fails along the perimeter of the group.

For block failure:

\[ Q_a = 2D(B + L) \times c_u + 1.3c_u N_c B L \]

where

- \( D \) = depth of pile penetration
- \( L \) = length of pile group
- \( B \) = breadth of pile group
- \( N_c \) = bearing capacity coefficient (taken generally as 9.0).

Whitaker (1957), in a series of model tests, showed that block failure will not occur if
the piles are spaced at not less than 1.5d apart. General practice is to use 2d to 3d spacings.

In such cases:

\[ Q_a = En Q_{up} \]

where

- \( E \) = efficiency of pile group (0.7 for spacings 2d–3d)
- \( Q_{up} \) = ultimate bearing capacity of single pile
- \( n \) = number of piles in group.

### 8.12.2 Settlement effects in pile groups

Quite often it is the allowable settlement, rather than the safe bearing capacity, that
decides the working load that a pile group may carry.

For bearing piles the total foundation load is assumed to act at the base of the piles
on a foundation of the same size as the plan of the pile group. With this assumption it
becomes a simple matter to examine settlement effects.

With friction piles it is virtually impossible to determine the level at which
the foundation load is effectively transferred to the soil. An approximate method,
often used in design, is to assume that the effective transfer level is at a depth of
2D/3 below the top of the piles. It is also assumed that there is a spread of the total
load, one horizontal to four vertical. The settlement of this equivalent foundation
(Fig. 8.24) can then be determined by the normal methods.

![Fig. 8.24](Transference of load in friction piles.)
Exercises

Note Where applicable the answers quoted incorporate a factor of safety equal to 3.0.

Exercise 8.1
A fine sand deposit is saturated throughout with a unit weight of 20 kN/m³. Ground water level is at a depth of 1 m below the surface. A standard penetration test, carried out at a depth of 2 m, gave an N value of 18. If the settlement is to be limited to not more than 25 mm, determine an allowable bearing pressure value for a 2 m square foundation founded at a depth of 2 m.

Answers 460/2 = 230 kPa (N ≈ 40)

Exercise 8.2
A strip footing 3 m wide is to be founded at a depth of 2 m in a saturated soil of unit weight 19 kN/m³. The soil has an angle of friction, φ, of 28° and a cohesion, c, of 5 kPa. Groundwater level is at a depth of 4 m. Determine a value for the safe bearing capacity of the foundation. If the groundwater level was to rise to the ground surface, determine the new value of safe bearing capacity.

Answer 459 kPa; 249 kPa

Exercise 8.3
A 2.44 m wide strip footing is to be founded in a coarse sand at a depth of 3.05 m. The unit weight of the sand is 19.3 kN/m³ and standard penetration tests at the 3.05 m depth gave an N value of 12.

(i) Determine the safe bearing capacity of the foundation if settlement is of no account.
(ii) Determine the allowable bearing pressure if settlement of the foundation is not to exceed 25 mm.

Answers (i) 1300 kPa, (ii) 300 kPa

Exercise 8.4
A single test pile, 300 mm diameter, is driven through a depth of 8 m of clay which has an undrained cohesive strength varying from 10 kPa at its surface to 50 kPa at a depth of 8 m. Estimate the safe load that the pile can carry.

Answer 60 kN
Exercise 8.5

A continuous concrete footing ($\gamma_c = 24 \text{ kN/m}^3$) of breadth 2.0 m and thickness 0.5 m is to be founded in a clay soil ($\phi_u = 0^\circ; c_u = 22 \text{ kPa}; \gamma = 19 \text{ kN/m}^3$) at a depth of 1.0 m. The footing will carry an applied vertical load of magnitude 85 kN per metre run. The load will act on the centre-line of the footing.

Using Eurocode 7 Design Approach 1, determine the magnitude of the over-design factor for both Combination 1 and Combination 2.

Answer 1.53 (DA1-1); 1.56 (DA1-2)

If you were to include depth factors in the design procedure, what would be the revised value of the over-design factor for each combination?

Answer 1.79 (DA1-1); 1.81 (DA1-2)

Note: Adopting depth factors in the design will invariably lead to higher values of over-design factor.

Exercise 8.6

A rectangular foundation ($2.5 \text{ m} \times 6 \text{ m} \times 0.8 \text{ m}$ deep) is to be founded at a depth of 1.2 m in a dense sand ($c' = 0; \phi' = 32^\circ; \gamma = 19.4 \text{ kN/m}^3$). The unit weight of concrete $= 24 \text{ kN/m}^3$. The foundation will carry a vertical line load of 250 kN/m at an eccentricity of 0.4 m.

By following Eurocode 7, Design Approach 1 establish the proportion of the available resistance that will be used.

Answer 16 per cent (DA1-1); 24 per cent (DA1-2)

Note: The proportion of available resistance that will be used is determined by taking the reciprocal of the over-design factor.
